INTERNATIONAL GROUP ON RELIABILITY

Guest Editors

This special issue on "Reliability: Theory and Applications" contains high quality articles on innovative approaches to climate change risk reduction. All articles were presented at the 6th Eurasian Conference "Innovations in Minimising of Natural and Technological Risks of Climate Change: Methodology and Practice" held under the auspices of COP-29 in Baku, Azerbaijan on 27-29 November, 2024.

We would like to thank all RISK-2024 conference participants from 38 countries for submitting papers and the reviewers for their efficient work in evaluating the submissions. We sincerely appreciate their excellent and timely responses.

The Guest Editors are also very grateful to the Secretary, Dr. Alexander Bochkov, for his continued support and constructiveness in the process of reviewing and preparing the proposal for the Special Issue. We hope that this special issue will make a significant contribution to improving the scientific field of assessment, analysis and management of natural and anthropogenic risks of climate change.

DECLARATION

of the Sixth Eurasian Conference RISK-2024 under the auspices of the UN COP29 "Innovations in Minimizing of Natural and Technological Risks of Climate Change: Methodology and Practice" 27-29 November 2024, Baku (AZERBAIJAN)

Global climate change is the greatest existential threat to human existence. The COP29 conference, like the Stockholm conference 1972, discussed this threat from the perspective of the countries (top-down), while the RISK-2024 conference discussed the same problem from the perspective of the scientific community and experts (bottom-up), thus complementing the UN COP29. This declaration reinforces the decisions of the UN COP29 in terms of the involvement of every Earth inhabitant in everyday purposeful activity related to problem-solving and attaining the common goal of reducing the negative impact of technological greenhouse gas emissions on the Earth's biosphere.

We, the participants and organizers of the 6th Eurasian Conference "Innovations in Minimizing of Natural and Technological Risks of Climate Change: Methodology and Practice" (RISC-2024) under the auspices of the UN COP29 from 38 countries around the world, meeting in Baku (Azerbaijan) from 27 to 29 November 2024, understanding the need to develop a unified risk-based approach and to consolidate common principles of sustainable development in preserving and improving the human environment, proclaim that:

- Preserving and improving the quality of the human environment under the climate change is an important issue affecting the well-being of people and the economic development of all countries of the world, an expression of the will of their people and the duty of all governments.
- We reaffirm our commitment to play an active role in the formation of national and interтnational mechanisms to ensure the security of population and territories. We consider it important to involve all stakeholders in the analysis, assessment and management of the climate change risks.
- We express our concern about the increasing greenhouse gases emissions into the Earth's atmosphere and the scale of loss and damage from accidents and disasters caused by climate change and man-made disasters and call for joint efforts of scientists and specialists of the Eurasian countries to improve the effectiveness and responsibility of solutions to minimize the risks of natural and man-made emergencies.
- The Eurasian Risk Platform, created by the company "AMIR Technical Services", having the experience of successfully holding six multilateral conferences, which became an effective platform for generating ideas and meanings of risk theory, searching for ways to stimulate innovations to minimize existing and emerging climate change risks, claims to be the international coordinating center of the Green Planet 2060 Initiative Root Movement (GPM 2060).
- We define the objective of the Green Planet 2060 initiative movement as the development of an interdisciplinary approach to the risk-oriented management of intelligent socio-technical infrastructures and territories and the search for sustainable development pathways in the context of climate change.
- In order to achieve this goal, the Green Planet 2060 initiative movement intends to contribute to the accumulation and dissemination of innovative and advanced knowledge on climate, natural and anthropogenic risks, as well as technologies and methods for (1) minimizing greenhouse gas emissions, (2) local and atmospheric carbon dioxide sequestration, (3) advanced development of low-carbon energy sources, (4) methods for ensuring safety of agricultural soil and maintaining its fertility, (5) innovative approach to identifying various climate-related risks, and (6) developing innovative mitigation and adaptation approaches to climate change.

- Sustainable development and risk management are imperative research areas that overlap and influence each other. Sustainable development is defined as development that meets current societal needs without compromising the ability of future generations to meet their own needs.
- Risk management, in turn, plays a key role in achieving sustainable development by making science-based decisions, minimizing negative impacts on ecosystems and communities, and enhancing their sustainability.
- The Green Planet 2060 innovation movement will promote mutual understanding and deepen professional interaction between industry stakeholders, scientific and academic institutions to minimize the risks of climate change and ensure the safety of the population and sustainable social and economic development of the regions of the Eurasian continent.
- We believe it is important to establish an organic link between minimizing the risks of climate change, emergencies on the one hand and sustainable development of countries, on the other hand, involving all stakeholders and the general public in the analysis, assessment and management of risks, including the popularization of the ideas of sustainable development in all media, educational and scientific environments.
- We fully support further development of innovative approaches and actions within the framework of multilateral and regional cooperation and exchange of best practices and solutions in the field of climate change risk reduction based on the main decisions and outcomes of the UN COP29.
- The Eurasian Risk Platform, AMIR Technical Services, Gnedenko Forum, Research Center *Reliability and Safety of Large Systems* Ural Branch, Russian Academy of Sciences are launching the International Journal of Sustainabil-ity and Risk Management, which aim is to publish the latest theoretical and empirical re-search and commentary on communication, regulation and risk management with the sus-tainable development paradigm.

Abstract

The paper (opening keynote lecture of the 6-th Eurasia Risk 2024 Conference) examines, from the interdisciplinary positions of the infranetics umbrella science and MABICS convergent technologies, the problem of climate change as a generally recognized consequence of the heating of the Earth's atmosphere due to uncontrolled emissions of greenhouse gases (GHG) by the global infrastructure (GI) – the second, artificial, nature created by man. An overview is given of the state of the problem of reducing the carbon footprint (CF) of the global system of infrastructure systems, which, on the one hand, ensures the sustainable development of the mankind, and on the other hand, is the main cause of global warming, which, if not combated, poses an existential threat to humanity. It is shown that the problem of restoring and maintaining the homeostasis of planetary ecology consists in ensuring a balance between two opposite processes – sustainable socio-economic development of the world community and greenhouse gas (GHG) emissions, by achieving net zero emissions. The problem of quantitative accounting, assessing and minimizing the infrastructures CF at all stages of their life cycle (LC), including diagnostics, monitoring, maintenance, recovery from accidents and disasters, is considered. Significant information gaps and scatter in CF estimates are noted, which indicate insufficient accuracy of the currently used methods. It is shown that it is necessary to develop a working algorithm for solving the global carbon balance equation considering climate change, according to the top-down scheme, which shows the contribution to the global CF of each infrastructure over time, according to the criterion of achieving zero CO_2 *emissions by 2060, in accordance with countries' obligations under the Paris Protocol of 2015.*

Keywords: global warming, global carbon budget, greenhouse gas emissions, economic and digital footprints of infrastructure, decarbonization, carbon offsetting

I. Introduction

The heating of the Earth's atmosphere has led to an increase in the frequency, strength and duration of geometeorological phenomena (drought, wind speed, precipitation amount), the emergence of new climatic phenomena (reduction of the ice cover of the Arctic Ocean, thawing of the Arctic tundra, accelerated melting of the Antarctic and Greenland ice, rising sea levels, thermal domes/islands), which have led to the emergence of new existential threats and risks, and imperatively requires a revision of almost all ideas about how to design and operate the global cyber-physical infrastructure of the 21st century in order to ensure its reliability, resilience and security.

The paper presents a system classification and structuring of greenhouse gas (GHG) emissions and absorption on a global scale. It analyzes the global, country, sector and corporate (dis)balance of the CF in the context of each individual infrastructure's CF during its creation, operation and disposal. It considers a risk-oriented problem of Pareto optimization of an infrastructure system based on its CF indicator, with given country, sector and/or corporate time-based restrictions on GHG emissions. It presents data on existing methods of GHG extraction from the planet's atmosphere and its burial at the bottom of deep oceans or in fractured rocks of the Earth's mantle (Nobel Peace Prize 2007).

The problem of preserving the vitality and fertility of agricultural lands and soils, which arose due to global warming and directly affects the food security of mankind, is also considered.

The role of the human factor in the problem of mitigating the consequences of the climate change when managing the second nature is considered. It is shown that all decision-makers (DMs) at all levels of the global, national, regional and corporate hierarchy, every inhabitant of planet Earth must be involved in solving this existential problem. It is necessary to find (in addition to existing ones) new ways to support, stimulate and finance all scientific, technical and organizational efforts aimed at solving this global problem.

At all stages of the presentation, an interdisciplinary approach to solving the problem is traced based on the use of convergent MABICS-technologies of the infranetics umbrella science.

II. Status of the problem: a brief review

We are interested in the problem of anthropogenic climate change as a generally recognized consequence of the heating of Earth's atmosphere due to uncontrolled emissions of greenhouse gases (GHG) by the global infrastructure (GI) – the second, man created artificial nature. A greenhouse gas (GHG) is a gas of natural or anthropogenic origin that absorbs and emits radiant energy in the thermal infrared range, causing the greenhouse effect (GE).

The main GHG is carbon dioxide (CO_2). Although other GHGs are more effective per molecule in warming the planet than CO_2, the enormous amount of CO_2 emitted by human activity and the fact that some emissions remain in the atmosphere for hundreds or thousands of years make CO_2 the single biggest problem in the fight against climate change. Emissions of all other GHGs are converted to carbon dioxide using special formulas and expressed in terms of mass of CO_2-eq. Carbon footprint is the amount of CO_2-equivalent that enters the atmosphere through human activity. Of the total estimated GHGs emitted into the Earth's atmosphere, about 90 % is due to human activities.

Without GHGs, the average surface temperature of the Earth would be about -18 °C, rather than the current average of +15 °C. The main GHGs in the Earth's atmosphere are water vapor (H_2O), carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), and ozone (O_3).

For a long time, the atmosphere contained a safe amount of GHGs, emitted by evaporation of the oceans, volcanic activity and forest fires. Human activity since the beginning of the Industrial Revolution (around 1750) has led to an increase in the concentration of carbon dioxide in the atmosphere by more than 50 % by now. The planet has become increasingly warm, and the threat of global warming has loomed.

At the current rate of GHG emissions, the Earth's temperature could increase by 2 °C by 2050, which, according to the UN Intergovernmental Panel on Climate Change (IPCC), is the upper limit that still allows avoiding "dangerous" levels of atmospheric heating [1]. It is necessary to reduce carbon emissions so that the observed increase in the average temperature of the Earth's atmosphere does not exceed the critical 1.5 °C. To do this, the global average human CF (in t CO_2-eq./person·year) must be reduced to 2.5t by 2030 and to 0.7t by 2050. Today, according to statistics from the Global Carbon Project [2], the CF of a US resident is 16.4t, the EU – 6.8t, China – 7.4t, and Russia – 12.5t. The global average is about 5 tons of CO_2-eq./person·year.

Signs of a climate crisis include heat waves, fires, floods and powerful storms, flooding of cities, extinction of biological species, drought and other natural disasters. If the situation is not changed, then very soon we will experience an increase in the frequency of natural disasters, the planet will have significantly reduced supplies of drinking water, existing desert zones will expand, outbreaks of epizootics, epidemics, infectious diseases, and famine will occur in many regions. In the most negative forecasts, all life on Earth may be under threat.

The anthropogenic factor has a huge impact on the manifestation of natural emergencies. Human activity disrupts the balance in the natural environment. Already now, the features of the global ecological crisis caused by the growth in the scale of use of natural resources are noticeably manifested. The main causes of natural hazards are:

- increasing anthropogenic impact on the environment;
- irrational placement of economic facilities;
- settlement of people in areas of potential natural hazard;
- insufficient efficiency and underdevelopment of hazard monitoring systems;
- absence or poor condition of hydraulic engineering, anti-landslide, anti-mudflow and other protective engineering structures, as well as protective forest plantations;
- lack and low rates of earthquake-resistant construction, strengthening of buildings and structures in seismically hazardous areas.

Currently there is a general understanding that natural disasters are a global problem that causes profound humanitarian shocks and are one of the most important factors determining sustainable economic development. Climate change increases the frequency and extremeness of severe weather events, which remain a major obstacle to sustainable development in cases where economic incentives for the development of hazardous areas do not exceed the expected disaster risks.

Extreme weather caused by climate change has pushed nearly 100 million people into hunger and increased heat-related deaths by 68 % among vulnerable groups. Globally, burning coal, oil, natural gas and biomass causes air pollution that kills 1.2 million people each year.

According to a new report published by the UN Office, the financial losses on global markets between 1998 and 2017 due to natural disasters increased by 251 %. In just 20 years, there were 7,255 major natural disasters in the world (i.e. one disaster per day). The most common disasters, based on the data in Fig. 1, are floods (43.4 %) and storms (28.2 %) [3]. Today, the concentration of CO_2 in the atmosphere is 0.04 % and this figure is growing. Global carbon dioxide emissions have reached 36 gigatons per year, and the average global temperature has already increased by 1.1 °C (in some places on the planet by 1.5 °C) [4].

III. Global carbon budget

The world's carbon budget includes all CO_2 emissions and absorption that are the direct or indirect result of human activity. The largest component of emissions comes from the combustion of fossil fuels (coal, oil and gas), which accounts for almost 90 % of all CO_2 emissions. The next smallest component comes from cement production. The remaining emissions come from land use changes (e.g. deforestation).

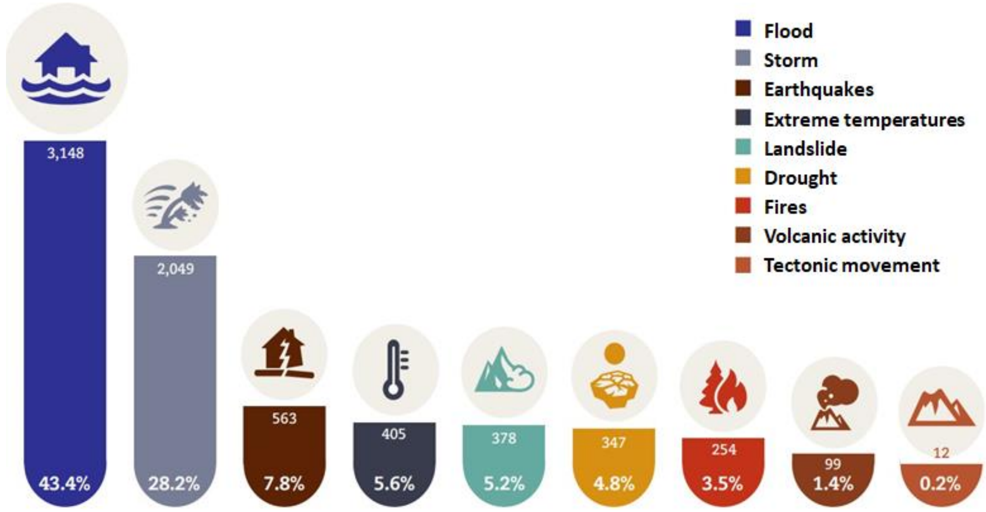

Figure 1: *Statistics of natural disasters in the world in the period 1998-2017*

The good news is that of all the CO_2 emitted by humans into the atmosphere, only about half remains in the atmosphere, causing climate change; the other half is removed by CO_2 sinks on land (vegetation through photosynthesis) and the oceans (through diffusion). The impact on climate change is therefore only half of what it would be without the help of these natural CO_2 sinks. Monitoring and predicting the evolution of CO_2 sinks allows to quantitatively estimate the speed of climate change.

The assessment of the global carbon budget is carried out by the Global Carbon Project (GCP), which unites more than 50 research institutes around the world that collect observations, maintain statistics, and develop global models for annual updating and improvement of the carbon budget. The key point of the GCP Global Carbon Budget 2023 report [2] is the conclusion:

- If current CO_2 emissions levels continue, the remaining carbon budget for a 50 % chance of limiting warming to 1.5 °C could be exceeded in 7 years, and for 1.7 °C in 15 years;
- Returning global temperatures below these thresholds once they are crossed will require a massive increase in carbon dioxide removal after net-zero global emissions are achieved.

IV. The Role of the global infrastructure associated with climate change

Anthropogenic heating of the Earth's atmosphere has led to the intensification of existing and the emergence of many new climate phenomena that threaten the sustainable development of regions, territories, countries and continents, as well as to the destabilization and destruction of the Earth's ecosystem. This heating has already affected the astronomical parameters of the Earth as a planet. Typical examples of such phenomena are:

- Rising sea levels caused by melting Antarctic and Greenland glaciers will eventually flood coastal regions and cause the disappearance of a number of Pacific island-states.
- Changes in precipitation patterns, leading to desertification and an increase in floods, hurricanes and tsunamis.
- Decreased crop yields and, consequently, a food crisis and famine.
- Lack of drinking water.
- Death of flora and fauna.
- Slowing down of the Atlantic Meridional Overturning Circulation (AMOC) conveyor belt as new freshwater flows from melting Greenland ice upsetting the existing balance of salt and fresh water in the circulation. Scientists fear that if the engine slows too much, it could stall, changing weather patterns (for the worse) for billions of people in Europe and the tropics. The

timing of such a tipping point is not yet predictable.

- A decline in the West African monsoon could transform tropical forests into grassy savannas.
- The thawing of the Arctic tundra, accompanied by the appearance of *batagaykas* – giant funnels (craters) in the Siberian tundra, which were apparently caused by huge bubbles of methane from melting clathrates (methane ice) erupting onto the surface. The first of these craters, discovered in 2014, was 30 meters in diameter and more than 70 meters deep, which gives some idea of the force of the eruption and the pressure of the methane accumulated beneath it. Batagayka is a newspeak, comes from the word Batagay – the name of a city built in the Chersky Ridge area in the Verkhoyansk region of Yakutia (Russia) for tin deposit developers. In 1969, geologists discovered the largest Batagay permafrost crater in the world near this city, or Batagayka (nicknamed in the media – Gates of Hell) [5].

As the soil thaws, the methane ice melts quite fast. Scientists believe that of all the possible events that could push the world toward abrupt, catastrophic, and irreversible climate change, only one—clathrate release—poses an immediate potential threat. Extraction of methane from seafloor clathrates could trigger massive underwater landslides and subsequent tsunamis.

To have a real chance of avoiding catastrophic climate change, it is not enough to slow the process; we must find a way to reverse it. This means removing CO_2 from the atmosphere and, ideally, returning the planet's atmosphere to pre-industrial CO_2 levels.

Effective carbon capture and storage can provide zero-emissions electricity, as renewable energy does now. But this is not enough to stop the runaway climate change that climate scientists believe may be underway. More must be done, namely (1) removing carbon from the atmosphere and (2) breaking the vicious cycle of methane release from the melting permafrost.

Virgin Enterprises founder Richard Branson launched the largest $25 million science prize ever in 2007 for a way to extract one gigaton (a billion tons) of carbon from the atmosphere each year. There are currently 11 finalists working toward that goal [6].

One of the fastest ways to capture atmospheric carbon is to grow fast-growing algae that can be turned into biochar through pyrolysis. This could go beyond zero human emissions and reduce methane emissions in the Arctic, but it would require a significant increase in the price of the carbon sequestered in this way to make it possible. The funds needed to do this, according to the Paris Agreement, could come from the developed world, which must raise (according to the COP 29 Resolution) $300 billion a year (by 2030) to help poorer nations achieve sustainable development.

On a planetary scale, the permafrost layer of the Earth contains about 1.6 trillion tons of CO_2—about twice as much as the Earth's atmosphere currently contains. Scientists call this carbon, made up of plants and animals that froze before they could decompose, *deep legacy carbon* [7]. All of this creates a new, previously non existing threat of collapse for the entire Arctic infrastructure: port facilities, railways, roads, airports, oil and gas pipelines, LNG plants, buildings and structures

(Figs. 2, 3, a, b [8]):

- Thermal domes (islands), not only in countries with a hot climate, but also in regions with a moderate climate (for example, East Canada), where the temperature reaches +50 °C and + 40 °C and higher, respectively, and lasts for several weeks, including at night. This leads to a decrease in human cognitive abilities, and to a mass manifestation of subresilience of people living under such a dome (on such an island), and corresponding expenses to cure this illness;
- Change in the relief of the Earth's surface;
- Change in the tilt of the Earth's rotation axis due to the melting of Antarctica ice;
- Increase in the time of the Earth's daily rotation (yet, by several milliseconds);
- Change in the dynamics of the Earth's crust, its interaction with the mantle and the Earth's surface, which must be considered for achieving needed accuracy of space navigation;
- Rising ocean temperatures are causing corals to expel the symbiotic algae that live inside their tissues. This bleaching is fatal to corals. Scientists predict that even if humanity quickly takes action to curb global warming, 70 to 90 percent of today's reef-forming corals could die in the coming decades. If not, the loss could be 99 percent or more;
- Deforestation of the Amazon could reduce rainfall in the region, causing the remaining forest to degrade and turn into grassy savannah. Researchers estimate that by 2050, a good half of today's Amazon forests could be at risk of this fate.

I. Classification of environmental emergencies associated with changes in

Land conditions:

- intensive soil degradation;
- catastrophic subsidence, landslides, collapses of the earth's surface due to subsoil development or mining;
- the presence of heavy metals and other harmful substances in the soil more than maximum permissible concentrations;
- depletion of non-renewable natural resources;
- overflow of storage facilities (landfills) with industrial and household waste, pollution of the environment by them.

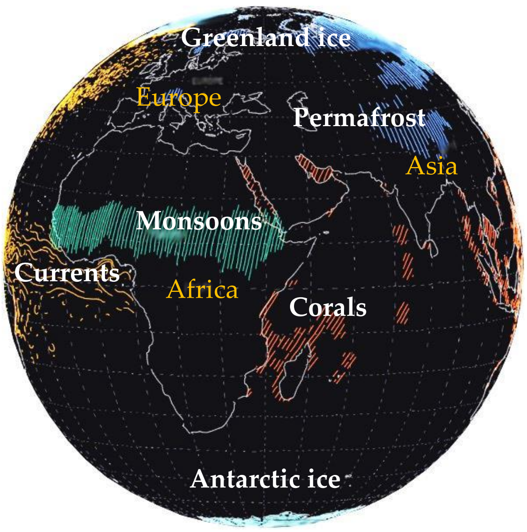

Figure 2: *Changes in the Earth's ecosystem because of global warming*

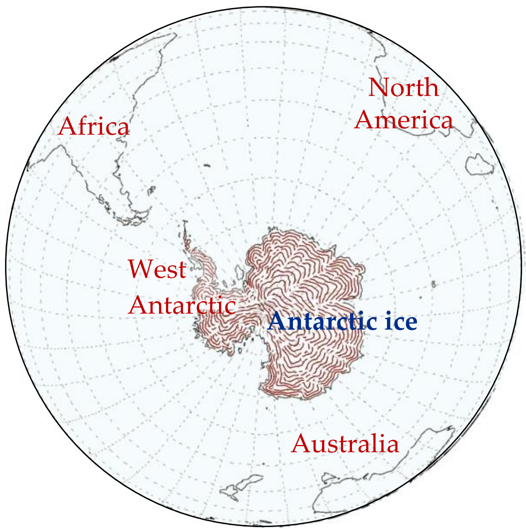

Figure 3: **a.** *Changes in the Earth's ecosystem because of global warming*

Figure 3: b. *Changes in the Earth's ecosystem because of global warming*

Composition and properties of the atmosphere:

- abrupt changes in weather or climate because of anthropogenic activity;
- temperature inversions over cities;
- severe oxygen starvation in cities;
- significant excess of the maximum permissible level of urban noise;
- exceeding the maximum permissible concentrations of harmful impurities in the atmosphere;
- formation of a vast zone of acid precipitation;
- destruction of the ozone layer of the atmosphere;
- significant change in the transparency of the atmosphere.

Composition of the hydrosphere:

- a sharp shortage of drinking water due to the depletion/ pollution of water sources.

II. The global carbon footprint (GCF)

The main emitting sectors in both the global and national economies are: (1) energy, (2) industry (non-energy processes), (3) agriculture, forestry and land use, and (4) waste disposal and recycling. The contributions of each sector, as well as the shares of subsectors of industries, to global emissions (according to World Resources Institute (WRI) data for 2016 [9]) are graphically presented in Figs. 4, 5.

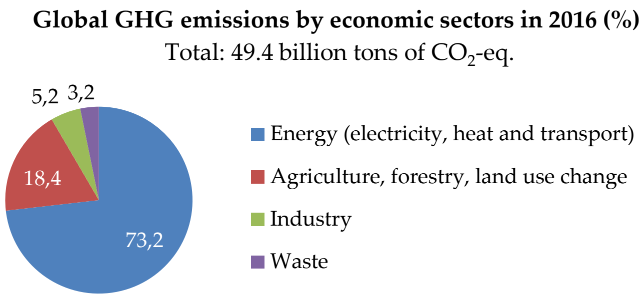

Figure 4: *Distribution of global greenhouse gas emissions (GGHG) by economic sectors in 2016 (%)*

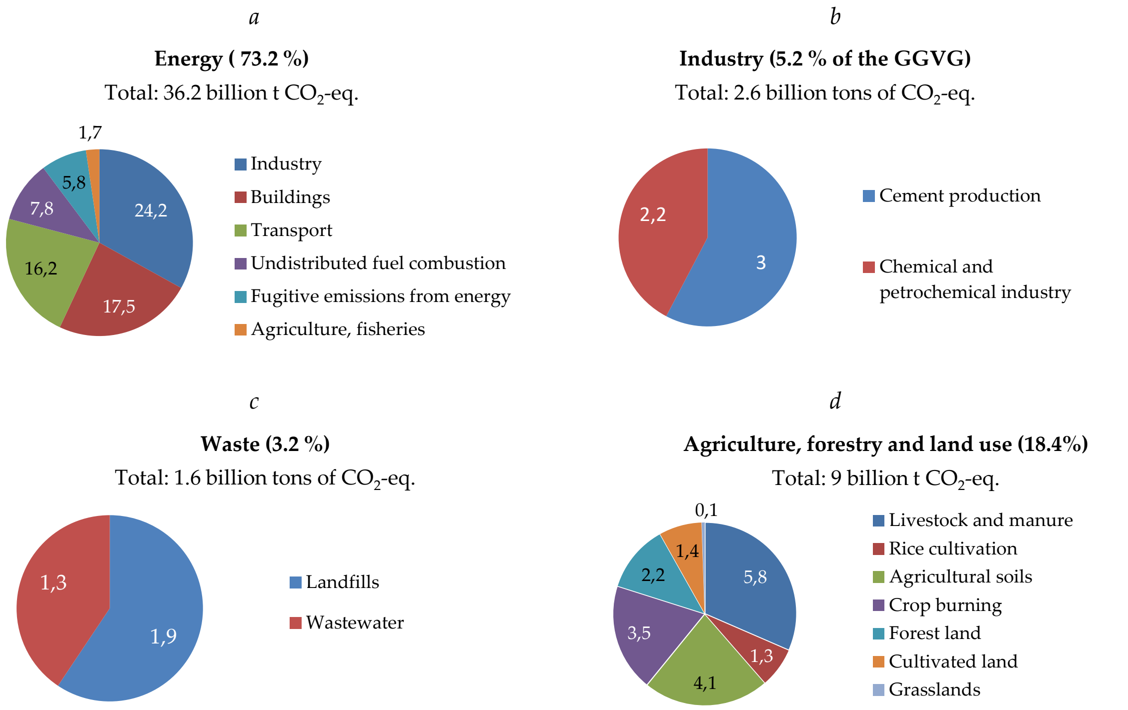

Figure 5: *Distribution of GHG emissions in 2016 (% of the GGHG):*
a – in the energy sector; b – in the industrial sector; c – in the waste sector; d – in the agriculture, forestry and land use change

The global carbon footprint of the world for a period t is the sum of the carbon footprints of all countries for the same period *t*:

$$CF_{\text{glob.}} = \sum_i CF_{\text{country}} , \qquad (1)$$

where $CF_{\text{glob.}}$ is the global CF, CF_{country} is the CF of the *i*-th country.

According to the European Commission's GHG data (EDGAR – Emissions Database for Global Atmospheric Research), in 2023 the global economy produced 52.9629 billion tons of CO_2-eq. [10]. The distribution of countries' contributions to the global CF is presented in Fig. 6.

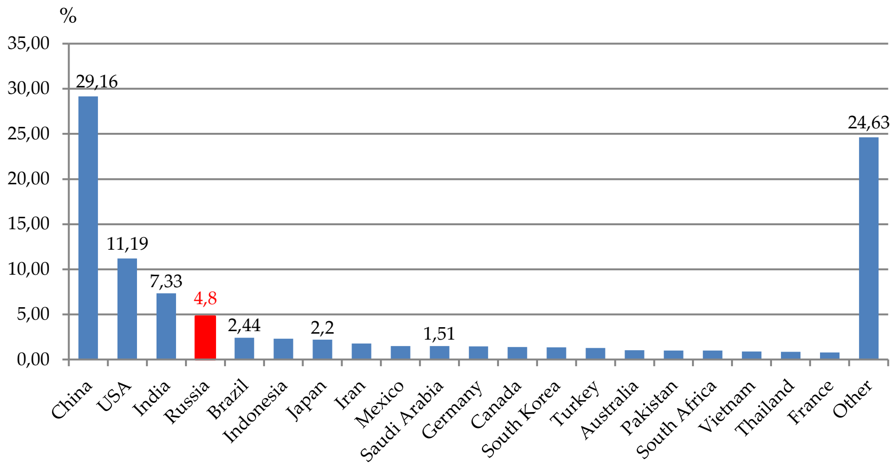

Figure 6: *GHG emissions by country in 2022 (% of global emissions)*

The GCF can also be represented as the sum of emissions from all sectors of the global economy:

$$CF_{\text{glob.}} = \sum_i CF_{\text{sector}} , \tag{2}$$

where CF_{sector} is the CF of the i-th sector of the world economy.

A country's GHG emissions are formed from emissions from all sectors of its economy:

$$CF_{\text{country}} = \sum_i CF_{\text{s},i} , \tag{3}$$

where $CF_{\text{s},i}$ is the GHG emission of the i-th sector of the country's economy.

The GCF, expressed in terms of country sector emissions, can be written as

$$CF_{\text{glob.}} = \sum_i \sum_j CF_{i,\text{s},j} , \tag{4}$$

where $CF_{i,\text{s},j}$ is the GHG emission of the j-th sector of the economy of the i-th country.

The contributions of economic sectors of Russia, as well as the shares of subsectors of industries, to total country emissions are graphically presented in Figs. 7, 8 [11].

Russia. GHG emissions by economic sector in 2020 (%)
Total: 2051.4 million tons of CO_2-eq.

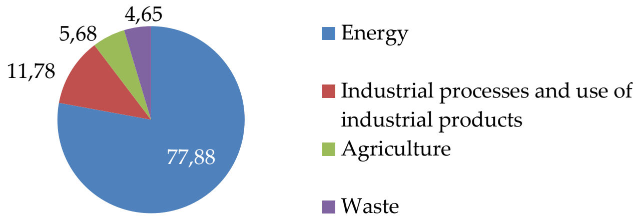

Figure 7: *Distribution of GHG emissions by economic sectors of Russia in 2020 (%)*

a *b*

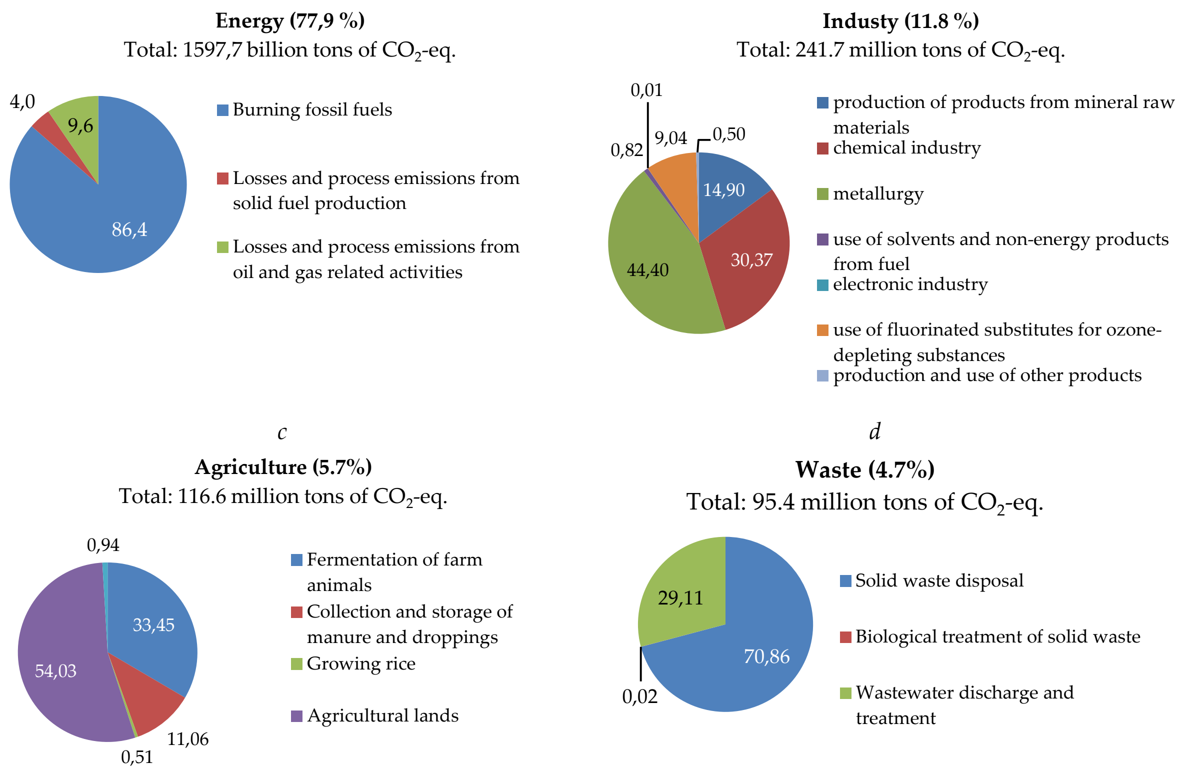

Figure 8: *Distribution of GHG emissions of Russia in 2020 (% of total CF):*
a – in the energy sector; b – in the industrial sector; c – in the agriculture; d – in the waste sector

V. Tasks of modern risk analysis of infrastructures in the context of climate change

The awareness that any human action is inevitably accompanied by an ecological trail, carbon emissions, economic and social footprint, allows setting and solving tasks of modern risk analysis in a new way. First, the CF must be considered as a planetary/country/industry boundary/maximum permissible condition (BC/MPC) acceptability of creating and operating each specific socio-technical system/infrastructure.

Infrastructure design must explicitly consider the impact of climate change on the magnitude of loads, impacts and any other stressors on the system being designed to prevent future incidents and accidents due to failure to consider increased impact values due to climate change. It is necessary to develop:

1) stochastic load and impact models, in the context of considering king-dragon events using heavy-tailed PDFs, as well as advanced degradation models of materials and structures;

2) risk-based design and maintenance standards for buildings and structures for thermal, wind, wave loads and impacts, and

3) full life cycles that consider climate change and the size of the carbon (as well as economic and digital) footprint of each infrastructure.

Particular attention should be paid to thermal loads in the Arctic Zone of the Russian Federation (AZRF), where the rate of warming is twice as high as the rate of global warming. Maintaining the reliability, resilience and safety of critical and strategic infrastructures in the context of global warming requires ever greater resources. This objectively reduces the economic efficiency of the oil, gas and transport sectors located in the AZRF.

A feature of modern risk analysis is that more and more attention is paid to the integrated economic consequences (damage) from undesirable events associated with a decrease in the physiological, cognitive and social abilities of an individual (and the affected community as a whole) over time from such stressors as active radiation, mass poisoning with chemicals (i.e., pesticides used in Vietnam), post-traumatic syndrome, etc. This problem is studied in the theory of sub-resilience.

I. Full life cycle (FLC) of the infrastructure

In the context of climate change, risk analysis must be carried out based on the FLC of the infrastructure/system/network. This relatively new task has a short history of its development.

In essence, the FLC is a forecast scenario for the entire period of the system's existence – from conception to disposal. The exception is infrastructures that have no visible end to operation. They exist almost forever: large cities, railways and highways, seaports, etc.

For a qualified and consistent assessment of the ecological/carbon footprint of the global artificial nature (GI), it is necessary to conduct a specific FLC analysis of each global infrastructure component (GIC) to assess (1) the magnitude of the ecological footprint and CF of the GIC as a random function of time and (2) its contribution to the global CF, influencing climate change on the planet.

The full life cycle of any GIC consists of following stages:

I) production of materials from which the GIC will be manufactured (extraction of raw materials to produce materials is usually not considered in the calculation of the CF);

II) production of the GIC;

III) construction of the GIC, including transportation, welding, installation of equipment, protection from external influences, acceptance tests;

IV) operation of the GIC in a stationary mode, including scheduled and unscheduled diagnostics, monitoring, technical repairs, maintenance, as well as restoration of the infrastructure after each accident, emergency or disaster;

V) recycling/disposal of the GIC after the end of its operation.

The infrastructure CF is an indicator of the environmental efficiency of its use at all stages of its LC and is therefore of great interest to the public and investors. Decision makers (DMs) when deciding on GI operation methods should (in the context of the Paris Protocol) separately consider the sizes of the current and the cumulative CF they create and the discounted cost of their neutralization, considering the impact of climate change.

In the conditions of dynamic multifactorial uncertainty of the modern world, the management of the GIC is carried out according to safety and risk criteria. In this case, the target function (TF) of risk management is reduced to minimizing the generalized cost of operating the GIC over the period "from conception/cradle to grave".

The problem of managing the GIC risk is posed as a problem of optimizing the target function, which should adequately reflect the total NPV of costs during its entire LC for:

1) creating and disposing GIC;

2) technical maintenance, repair and restoration due to possible emergency situations;

3) restoring the disturbed (due to system operation) ecological balance of the environment;

4) compensating the system's CF;

5) restoring lost human health and monetary compensation for the possible loss of lives and limbs during the GIC operation.

In the most general case, the problem of determining the man-made risk, interpreted as the product of the probability of failure (POF) and its consequences (losses/damage), expressed in monetary form, is formulated as a problem of Pareto-optimizing the target function, which is reduced to the integral cost of owning the GIC over its FLC:

$$_{\text{GIC}}C_{\Sigma} = C_{\Sigma,c} + C_{\Sigma,in} + C_{\Sigma,r} + C_{\Sigma,cf} + C_{\Sigma,hl}\,. \tag{5}$$

Here $C_{\Sigma,c}$ is the total cost of design, construction and commissioning of the GIC, as well as its disposal after the end of its service life; $C_{\Sigma,in}$ is the total cost of all inspections on the GIC life cycle; $C_{\Sigma,r}$ is the total cost of all repairs/restorations during the life cycle of the GIC, including after accidents and disasters; $C_{\Sigma,cf}$ is the total costs of compensation for damage from CF; $C_{\Sigma,hl}$ is the cost of restoring lost human health and the amount of monetary compensation for possible loss of lives and limbs during the GI life cycle.

When solving the problem of assessing and minimizing the CF size, it is necessary to consider following circumstances.

The size of the CF when creating the GIC is determined by the facility design goals; at the same time, the CF size is subordinated to these goals and cannot be a limiting factor. It follows from this that compensation for the CF caused by the construction and commissioning of the GIC may require the use of special financial instruments (for example, planting a certain number of fast-growing and highly CO_2 absorbent tree species). At the same time, the size of the CF when utilizing such a GIC is also a certain function of its original goal.

The main CF occurs during the operation of the GIC. It is a function of the volume and quality of diagnostics, monitoring, maintenance, as well as the consequences of GIC pipelines and vessels depressurization because of incidents, accidents and disasters.

Since all these operational events are modeled when constructing a set of GIC life cycle scenarios required to assess and minimize operational risk, the value of the CF is obtained as a natural consequence of the scenario under consideration. In this case, minimization of the CF for each virtual violation of the integrity of the GIC pipeline or vessel is possible in the process of making the next decision. This allows for effective management of the CF size by selecting optimal system design, inspection technologies, scheduled repairs, and restoration of GIC after depressurization or accident.

II. General algorithm for assessing the carbon footprint of a GIC over its life cycle

Since the sectoral CF is formed by individual infrastructures of companies/states, its reduction is accomplished by reducing the CF of each infrastructure that comprises the sector, starting from the initial stage of the GIC life cycle – the production of its structural components and the construction itself. By analogy with the name of the life cycle stage, the emissions of this stage are called initial CF of the GIC.

The design CF of an infrastructure is the CF emitted during its construction and normal operation, without accounting for any unplanned emissions due to accidents and subsequent restorations. For newly designed facilities, this value will be legislatively reduced. This will demand using new low-carbon technologies for building the structures, improved risk-oriented methods of facility operation, and advanced technologies for capturing the carbon emitted by the GIC.

In general, the calculation of the GIC CF considers emissions of all types of GHG, as well as indicators of energy expended per unit of production generated at all stages of its LC.

VI. Methods for reducing atmospheric carbon masses

There are two ways to decarbonize the Earth's atmosphere: through natural CO_2 absorbers and through technical and economic measures.

Natural CO_2 absorbers are:

- Healthy forests;
- Marsh and peat ecosystems (main absorbers of atmospheric CO_2);
- Brown algae.

Technical and economic measures are:

- Sequestration directly at plants and enterprises emitting GHGs;
- Minimization of fugitive gas leaks;
- Renewable energy sources;
- Alternative (low-carbon hydrogen) fuel;
- Use of electric vehicles, electric and hydrogen aircraft;
- Technologies for removing CO_2 from the atmosphere;
- Policy of "green" loans.

VII. Nuclear power carbon footprint

In nuclear power, the fulfillment of the undertaken obligations to reduce CO_2 emissions and achieve carbon neutrality is realized by replacing *dirty* electricity with *environmentally friendly* electricity.

The production of 1 kWh of electricity by burning coal produces 1700 g of GHG; when burning natural gas, the emission is about 900 g; at a hydroelectric power station – about 50 g; at a wind power plant – about 50 g; at a solar power plant – about 100 g; for nuclear energy – from 2 to 130 g CO_2-eq./kWh, with an average value of 29 CO_2-eq./kWh [12].

I. Recommendations for reducing the nuclear fuel cycle emissions

- When mining uranium, it is recommended to carry out underground leaching (characterized by the lowest energy and material costs).
- In the process of ore enrichment, gas centrifugation is more environmentally friendly than gas diffusion, since electricity from renewable energy sources is used.
- When choosing a site for the construction of a nuclear power plant (NPP), the potential loss of carbon by vegetation should be considered. During the construction period, the amount of materials and energy used can be reduced by reducing design redundancy, optimizing the design and shortening the construction period.
- During operation, it is recommended to use 5G and artificial intelligence (AI) technologies to enhance the digital transformation capabilities of the NPP, so that it can be operated with less dependence on personnel and, consequently, with lower emissions. At the end of the nuclear fuel cycle, a closed fuel cycle (CFC) strategy is recommended, where the spent nuclear fuel is reprocessed to extract unburned uranium U and accumulated plutonium Pu, which are then used to manufacture new fuel elements.

Effective management of carbon forests can potentially provide Russian nuclear power plants with conditions in which up to 20–25 % of all carbon emissions will be offset by an increase in phytomass in forests located within the sanitary protection zones of NPPs [12]. According to the statement by Russian Prime Minister M. Mishustin at the UN COP 29 conference on November 13, 2024 in Baku, Russian forests make up 20 % of the world's forest lands and absorb one billion tons

CO_2 per year.

VIII. Hydrogen energy carbon footprint

In hydrogen energy, the fulfillment of the undertaken obligations to reduce CO_2 emissions and achieve carbon neutrality is realized through the production of low-carbon hydrogen [13]:

- from fossil raw materials, including using CO_2 capture technologies;
- based on a nuclear power plant (with CO_2 capture);
- by water electrolysis based on a NPPs, hydroelectric power plants and electricity from power systems, subject to ensuring a low-carbon footprint, as well as
- based on renewable energy sources in those regions where the cost of hydrogen produced based on such sources is competitive.

IX. Carbon offset measures

1) Purchasing emission quotas from oil and gas transportation companies that have been able to reduce their emissions below established limits;
2) Investing in emission reduction projects (e.g., renewable energy sources) or offset projects (reforestation);
3) Purchasing certificates from specialized organizations that finance GHG emission reduction projects.

X. Measures to prevent accidental emissions

To prevent malfunctions and emergency situations of the GIC such as oil and gas pipelines, pressure and temperature monitoring are carried out – the main operational parameters of pipelines and pressure vessels, as well as their regular diagnostics and inspection to detect and assess deformations, welding defects, dents, damage to the protection of pipelines, pressure vessels, as well as possible leaks of natural gas.

The main reason for the cumulative growth of the CF of the gas-oil complex is the depressurization of its pressure vessels and pipelines, accompanied by the release of gas condensate or crude oil due to corrosion or crack formation. To reduce the likelihood of these risks passive or active preventive barriers are used.

Preventive barriers (i.e., corrosion allowance, external anti-corrosion coating, cathodic protection) reduce the probability of risks and the severity of their consequences. Since they (even all together) do not guarantee the GIC against depressurization, they are supplemented by parry barriers (i.e., leak detection system; emergency shutdown, accident elimination plan), which are designed to reduce the consequences of GIC depressurization [14].

The task of minimizing the CF of a specific infrastructure during its life cycle to achieve the planetary planned CF values (based on the Paris Protocol of 2015) is solved using the target function, which includes direct and indirect GHG emissions as a function of time. The CF value is managed by the Pareto optimization method based on risk-oriented monitoring and maintenance, with given values of the initial and final (considering climate change) CF permissible values. This formulation of the optimization problem allows each enterprise to implement the task of reducing CF, the likelihood and consequences of incidents, accidents and disasters.

XI. The agro-industrial complex carbon footprint

The CF of the agribusiness sector has its own specifics. When forests are cleared for agriculture (and land use changes occur), the carbon stored in the trees is released into the atmosphere as CO_2. These emissions need to be considered in life cycle assessment (LCA) studies of agricultural production. In Europe, CF and LCA information is becoming increasingly important for feed and food producers (in some countries, providing this data is already mandatory).

In addition, in recent years, soil security has emerged as a new paradigm for addressing sustainable soil management. Soil security is defined as maintaining and improving the world's soil resources so that they can continue to provide food and freshwater, make significant contributions to energy and climate sustainability, and support biodiversity conservation and the overall protection of ecosystem goods and services [15, 16].

The European Commission has identified the following seven soil functions that should be protected:

- Biomass production, including in agriculture and forestry;
- Storage, filtration and transformation of nutrients, substances and water;
- Biodiversity pool (habitats, species and genes);
- Physical and cultural environment for humans and their activities;
- Source of raw materials;
- Carbon pool;
- Archive of geological and archaeological heritage.

Food and nutrition security (FNS), like soil security, has its own parameters: availability, access, utilization, and stability.

Food security is becoming increasingly challenging over time due to changes in supply and demand caused by population growth, climate change and environmental conditions. For a nation, community or individual to be food secure, it must *always* have access to sufficient, safe and nutritious food to support an active and healthy life.

Accessibility is the physical availability of sufficient food of adequate quality. This aspect of food security is directly linked to agricultural management and the availability of land for crop production.

XII. Conclusions

- To achieve a zero-carbon balance on a planetary scale, it is necessary, using the Paris Agreement limits on country emissions, to establish maximum permissible emissions (MPEs) within each country for each industry and life activity.
- Within each economic sector, it is necessary to establish MPEs for each and every network infrastructure and system. These MPEs are limitations that must be considered when designing new and operating existing infrastructures. This introduces a limitation on the CF during diagnostics, monitoring, maintenance, recovery after an accident and disposal of infrastructures and their components. In addition, it becomes possible to estimate the CF size of each incident, accident and man-made disaster. All these values must be optimally minimized.
- Considering the Paris Protocol on reducing the carbon load and achieving carbon neutrality by all countries to reduce the temperature of the atmosphere by two degrees, risk analysis procedures carried out at the design stage of the GIC should not only assess their level of safety, but also provide an assessment of the project CF.
- At the stage of risk-oriented operation of the GIC, it is necessary to plan and implement organizational and technical measures to minimize the CF, by ensuring high reliability of the GIC according to its integrity criterion.
- The initial and boundary conditions on the infrastructure CF organically converge social and cognitive sciences with engineering mechanics, computer science and artificial intelligence, forming a MABICS-technology, under the umbrella science of infranetics.

- In connection with the above, it seems appropriate to initiate a research topic on assessing the magnitude of the emissions arising from leaks and accidents of the GIC, which do not currently fall under the Order of the Ministry of Natural Resources and Environment of the Russian Federation dated 05/27/2022 No. 371 [17].
- It is advisable to introduce mandatory certification of each GIC for its emissions. This certificate must be confirmed annually. This certificate allows monitoring emissions of all sectors of the national economy and the rate at which the country (and global) emissions approach zero emissions.
- Certification of all lands from the viewpoint of (1) the safety of their soils and vegetation, (2) biocapacity/productivity and (3) CF will allow forming of a "reference point" for assessing the population quality of life, and the quality of services and industries. Completion of the first point will allow assessing (apparently for the first time) the country's bioproductive capacity and its ultimate capacity to absorb pollution as a function of time.
- When assessing the financial availability of food, it is necessary to consider the region's life quality index (LQI); when assessing its transport accessibility the reliability of transport networks (primarily highways) has to be considered, and when assessing the availability of food in a store it is necessary to assess the reliability of the supply chain and the level of reserves over time with random demand.
- The *supply–demand problem* (analogous to the classical *load-resistance* problem of the structural reliability theory) as applied to the food security problem has its own specific characteristics: the demand for civilization products, primarily food, can be regulated by social instruments; supply (production of edible biomass) is solved by ensuring agricultural soil reliability and safety, using advanced AI-based agricultural technologies and probabilistic forecasting of crops.
- Risk managers and risk analysts must be prepared for climate change shocks (and their implications for artificial intelligence, politics, finance, energy systems, food and water supplies, and pandemics) in the next few years, not at some unspecified time in the future.
- The largest emissions in the life cycle of a GIC are generated during its construction and operation phases.
- The main way to reduce GHG emissions is by using of energy-efficient technology and process equipment (e.g., new generation gas pumping units with low-emission combustion chambers).
- The Russan oil industry should: (1) lobby for a carbon price that will help it take market share from coal faster, (2) ask the government for financial incentives to capture Arctic methane emissions, produce and sequester biochar; (3) minimize methane leakage throughout the gas supply chain; (4) identify financial incentives that will make capturing methane leakage from permafrost profitable; (5) explore ways to convert atmospheric carbon dioxide into biochar for long-term storage and (6) identify financial incentives that will make this profitable [5].
- The super task of decarbonizing the Earth's atmosphere is the creation of nature-like, low-energy technologies and low-temperature processes that imitate the efficiency of those observed in nature.

Abstract

Due to failures in adaptation to global climate change impacts and related risks of natural disasters the safety of human wellbeing, economic sectors, and infrastructure is challenged worldwide both in developing and developed countries. We analyze major features, trends and transformations in societal responses to adverse climate consequences and in global adaptation to escalating disaster risks attributed to climate variability. The focus is on the recently dynamic formation of international system of adaptive governance - an integral segment of global climate policy along with climate mitigation: its formation is based on cross-level coordination, interplay and interaction between its actors, and on combination of context-specific factors from different geographies. Recent shifts in international discourse on climate loss and damage which is among the key indicators in assessment of climate risks and responses are outlined; problems in its incorporation into the climate international regime under the UNFCCC and controversies in global North-South dialogue on climate responsibility, liability and compensation are explored. It is followed by analysis of the recent breakthrough in climate multilateral negotiations underway during the last three decades over the institutional architecture of climate adaptation regime and its mechanisms of international aid for climate risks reduction in the global South. Prospects for performance of the novel international financial mechanism under the UNFCCC, i.e. the multilateral Fund for climate loss and damage in most vulnerable developing countries are discussed, along with its expected contributions to sustainable development.

Keywords: climate risks, adaptation to climate impacts, adaptive governance system, international regime, Fund for loss and damage, international aid for sustainable development

I. Introduction

Today, climate change challenges are at the top of global risks agenda and active international discussion about design of possible responses to growing climate variability and its impacts on ecosystems and societies are among priorities within dynamic global discourse. According to the last *Global Risks Report* [1] during the recent years climate risks acquired stable ranking among top-5 global risks along with geo-political and socio-economic challenges to global sustainable development, to well-being of the planet and its residents. Combination of two major interlinked segments in the system of human responses to climate change, i.e. *mitigation* through limitation of greenhouse gases emissions (GHG), and *adaptation* through reduction of climate risks and societal vulnerability - are among its core attributes.

So far, certain imbalance in climate actions of the international community along these two tracks is noted. The priority is the innovative set of measures for emission reduction through global transfer to low carbon development to meet long-term targets of the 2015 Paris agreement to limit global warming by 1.5-2.0˚C by the end of the century. But, due to serious gaps in mitigation profile it might be rather difficult to achieve these ambitions[1]. As a result human society would be facing a challenge of *living with risks* of climate change. At the same time disproportionally modest attention has been paid to advances in human responses and to adaptation to climate impacts, particularly to emergency natural disasters such as floods, forest fires, heat-waves, cyclones, etc., and to slow on-set processes like sea level rise, desertification, permafrost destruction, etc. Until recently, this segment of climate policy and measures has been overlooked, and adaptation of countries, regions, economic sectors, infrastructure and communities worldwide has been proceeding too slowly, it had been underfinanced and poorly prepared. Disproportion in global climate financing is recorded: about one third of total climate finance is allocated to adaptation, while the rest is transferred to emission reduction actions [2].

The World Meteorological Organisation (WMO) warns that each consecutive year of the current decade has been warmer than the previous one, and this trend is accompanied by increase in intensity and scales of floods, heat waves, storms, droughts and wildfires. Safety of human wellbeing, economic sectors, and infrastructure are seriously challenged. Recent global loss and damage statistics alarm. In 2023 about 185 million people were affected by extreme events, while fatalities reported as 95 000 were of highest figure on record since 2010 [3]. Natural disasters culminated in US$380 billion world economic losses, and this year is considered as the 'most expensive' in the current century in terms of climate disasters mitigation costs. According to expert assessment future loss and damage mitigation costs might be rocketing.

These trends towards escalating climate risks are attributed to a combination of natural and societal factors: they are defined not only by exposure of countries and individuals to climate change impacts and related disasters depending on their geographical location, but also by unwise, or ineffective human actions. Settlements in river floodplains and flood prone marine coastal areas, violation of construction norms, failures in territorial planning often result in aggravated risks [4]. They are faced by all groups of countries worldwide independently from the level of socio-economic development; although their vulnerability might be inversely proportional to success in their sustainability advances and capacity-building for response action. Significant spatial variations from the standpoint of societal resilience, vulnerability and adaptation response are tracked globally. Climate action failure at various governance levels is also among important drivers: part of the reason - adaptation gaps to adverse climate change consequences worldwide. In some cases, 'black swans' and possible surprises from climate impacts might also be amidst a combination of factors, particularly due to high uncertainty in future scenarios of climate dynamics, its impacts on ecosystems, and results of natural and societal systems interaction.

Climate change bears cumulative consequences both for ecosystems and human systems. As a result it has societal implications, including for socio-economic development, human welfare, infrastructure and services, institutional and technological shifts. Our research suggests that a variety of climate change impacts worldwide envisage assessment of both - their negative consequences and potential development opportunities, although the former ones appear to be dominant. Among possible benefits, for example, might be a accelerating seasonal decline of the Arctic sea ice cover which possibly provides for new access to remote areas and transportation opportunities in the North. Today, the resilience of societies to climate change impacts is far from desired and vulnerability (sensitivity and deficit in response capacity) to harm from natural disasters has been growing both in countries of global South and global North. We base our discussion about climate change challenges and risks to the society on the International Panel on Climate Change (IPCC) approach according to which the risk is the potential for consequences where something of value is at stake and where the outcome is uncertain, recognizing the diversity of values. In the context of climate change impacts, risks result from dynamic

[1]. Meeting by the end of the century the Paris agreement's goal to limit global warming by 1.5°C requires reduction of world GHG emissions by 45% by 2030 (2°C - by 30%). Assessment of 192 climate national reports of its member-states according to standard criteria of 'nationally determined contributions' indicates that by 2030 the world emissions might be 58.7% higher than their base level in 1990.

interactions between climate-related hazards with exposure and vulnerability of the affected human or ecological system to hazards.

This article focuses on analysis of human responses to climate risks and how they are addressed through adaptive governance at local, national, international levels. In this package we concentrate on major features and trends in international adaptation system which is characterized by a combination of significant innovations along with serious gaps. It is being gradually shaped and *international regime for global climate change adaptation* is currently under formation, particularly within the 1992 United Nations Framework convention on climate change (UNFCCC) with its 2015 Paris agreement and related institutions.

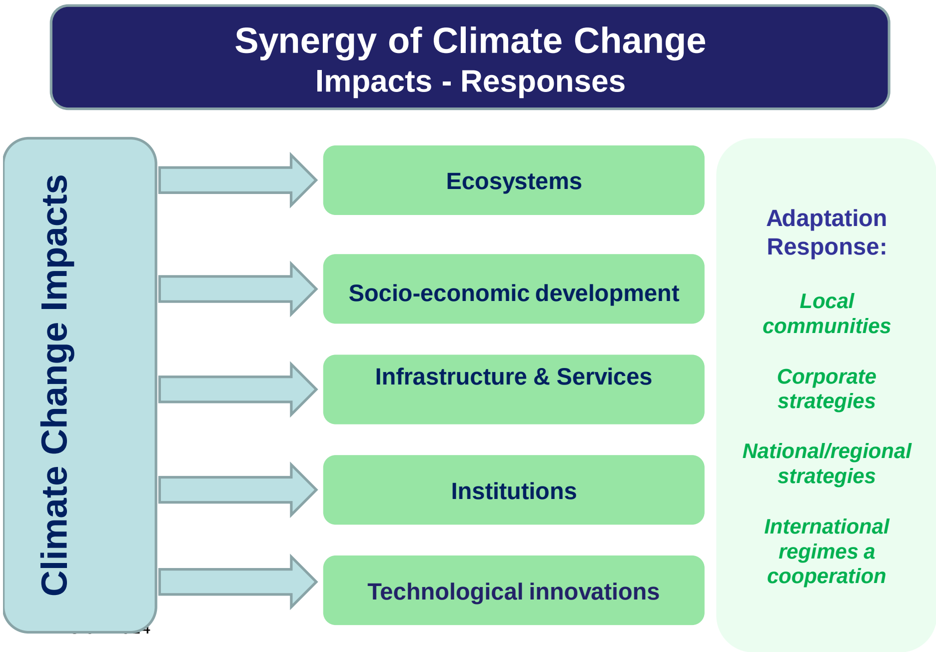

Figure 1: *Synergy of climate change impacts-responses*

II. Methods

A *mixed methods approach* was used in this study, including a combination of qualitative research methodologies and case studies [5]. Qualitative analysis drove the initial identification of major dimensions, trends, combination of drivers and general features of the current system of adaptive governance of climate change impacts [6]. Verification of its core attributes and exploration of their correlations (or deviations) with the major properties in formation of international regime on climate adaptation under the UNFCCC, including assessment of its design and features in implementation of its regulatory frameworks was undertaken. Qualitative approach was also used to help interpret and illustrate major findings. Case study analysis provided the evidence about approaches and practices in natural disaster risk reduction in a number of countries in Asia, and about trends in problem-solving in climate related risk reduction in case of floods as a result of (a) ice melt and sea level rise, and (b) regular river flooding. Application of polycentric approaches [7; 8] in analysis of adaptive governance system and its international frameworks allowed to unpack the causal linkages within the 'impact-response' governance chain, the drivers and limitations from the local contexts, interplay of actors and institutions. Its use application is s results are highly important for explanatory analysis and assessment of outcomes from cross-scale actions of actors and of instruments used for enhancing compliance both with the frameworks of international climate adaptation regime and domestic regulations. On the basis of assemblage thinking [9] we approached the quest of international coordination, integration, interplay of conflicting interests and compromises not only in climate policy decision-making but also towards meeting the 2030 sustainable development goals [10]. The list of research methods and approaches applied includes:

- Qualitative analysis
- Case-study research
- Polycentric approaches
- Assemblage approaches

This study aggregates our findings from a set of research projects in the field of sustainable development, international and regional cooperation in climate adaptation and disaster risk reduction, implementation and effectiveness of international environmental regimes. Among sources of information are data-bases of the UNFCCC, including documents and proceedings from the conference of the parties, reports of its Warsaw International Mechanism (WIM), the set of submitted eight national communications from Annex I and Non-Annex I parties and aggregated inventory data. A series of the recent international assessment reports on state-of- the-art in global and regional climate adaptation, IPCC reports, updates on climate change impacts and climate risks served as sources for analytical interpretation.

III. Results

This article contributes to research exploring the major features and trends in development of the new global system of adaptive governance dealing with human responses to climate change impacts, and particularly to extreme natural disasters which are resulting in regular annual growth of loss and damage worldwide. Its major innovation - formation of the international regime on adaptation to climate change, which is among the top challenges at the global risks agenda. Results presented for discussion are the following:

Our analysis indicates that adaptation to climate change impacts although being an equally important (along with mitigation) segment in global climate governance had not been its major priority until recently. As a result, the latest international assessments point at failures in adaptation response with safety of population, economic sectors and infrastructure being under risk worldwide, and particularly in vulnerable countries of the global South. Today, encouraging innovations in adaptation are starting to shape across different levels – international, regional, national and local, across groups of stakeholders and geographies. The system of adaptive governance emerges, and its design is rooted in synergy and coordination of responses to current and future climate risks and to development opportunities. It aims at taking into account and making flexible adjustments to the specifics of the environmental and socio-economic contexts in different geographies, combination of drivers and barriers, including possible 'black swans' effects with unforeseen consequences under high climate uncertainty, as well as causal linkages and interplay of actors and institutions involved in adaptation action.

Climate adaptation turns into a new important cluster in global architecture of interactions between the states and in international climate policy and measures. Today, this process is accompanied by (a) the transfer from concept to practice, and (b) dynamic formation of international regime on climate change adaptation with a set of principles, norms, rules and institutional procedures coordinated between its parties. It is progressing under the 1992 United Nations Framework convention on climate change (art.7) and its 2015 Paris agreement containing the adaptation regulations (art.42-65). Shifts towards implementation are enacted by its recent Framework for Global Climate Resilience in order to perform the Global Goal on Adaptation with its step-by-step strategy, concrete time-frames and instruments for adaptation action worldwide. In 2022 the breakthrough in adaptation regime was marked by the culmination in the global North-South climate negotiations which have been underway during the last three decades: the adaptation finance mechanism for international development with its multilateral Fund on Loss and Damage (FLD) to support adaptation and damage reduction in developing countries vulnerable to climate impacts was established.

We suggest that loss and damage (LD) attributed to impacts of climate change is among the core indicators in assessment of climate risks worldwide and in design of response adaptation, including the global level. So far, there is no unified definition of climate LD and expert approaches and perceptions within the ongoing international discourse are diverse, especially regarding concepts, typology, methods for cost estimate. The major controversy in the North-South climate dialogue is centered on the issue of climate responsibility, liability and compensation of LD attributed to climate change impacts for the developing countries; particularly conflicting approaches of the parties relate to interpretation of compensation of harm caused. They appeared to be a long-standing barrier in adaptation regime formation. By 2022 part of the impediments had been lifted via a compromise in North-South dialogue based on coordination of approaches on adaptation finance with establishing the mechanisms of international support for adaptation in most vulnerable developing countries. At the same time no accord had been reached on liability and compensation: Paris agreement includes general LD provisions, but it lacks jointly agreed norms on climate liability and compensation.

The newly established international climate finance mechanism with its multilateral FLD marks a special track in formation of international regime on climate adaptation, and advances in its financial mechanisms. It is to be seen how effective its performance would be after its mechanisms are enacted. But, it signals about creation of a niche for institutionalizing and channeling the international support for adaptation in the global South, which had been significantly underfinanced being about 10-18 times lower than the needs of the most vulnerable countries. It is supposed also to be an integral part in already quite diversified international system of climate finance with its specific focus on climate adaptation and international development cooperation through funding, technological support and domestic capacity building in developing countries vulnerable to adverse climate impacts. We conclude that international development funding should be always packaged with transfer of technology, competences and best practices, because as a single, although quite appealing instrument, it is not able to solve the complexity of international development problems and adaptation capacity building in recipients.

The role of this new adaptation finance mechanism and its FLD within the current constellation of international climate development agencies is supposed to be defined by its ambition to refine international adaptation funding channels and promote easier access to resources for its recipients, through involving innovative schemes for preferential funding, climate risk financial management, operational access to allocated funds in case of disaster emergencies. Among its functions – institutional coordination at the global level between international agencies involved in actions for climate LD reduction. The recent estimate of FLD total funding pledges from potential donors is quite modest so far in contrast, for example, to the Green Climate Fund with its record of mobilized funding ($ 12.8 billion). Fragmentation and insufficient coordination between climate development agencies could be considered as a significant flaw in their multilateral climate action. Despite the targeted annual international climate finance is planned to be increased up to US$ 100 billion level starting from 2025, the existing global profile indicates that there might be some concerns about its feasibility in practice. On the other hand, the existing assemblage and growing interplay of climate funds at various levels indicate at emerging global trend towards tighter partnerships between global agencies and organizations contributing to various aspects of climate adaptation and disaster risk reduction, including WMO, UNEP, UN Disaster Risk Reduction (UNDRR) and The Global Facility for Disaster Reduction and Recovery (GFDRR): the results of their combined efforts might be important in such priority areas as enhancing climate resilience, global systems of operational forecasting, Big Data, climate services and exchange of adaptation knowledge. Contribution of such partnership for meeting the 2030 global sustainable development goals might be among its effective outcomes.

IV. Discussion

I. Adaptive governance system

Adaptation is the process of adjustments of the society to actual or expected climate and its effects in order to either lessen or avoid harm, or exploit opportunities for sustainable development [11]. Ensuring safety of the population, critical infrastructure and economic sectors is the top priority of the emerging global *adaptive governance* system and its actors. Since recently adaptation instruments and measures are becoming diverse worldwide, but still adaptation is proceeding too slowly and adaptation practices are highly fragmented to effectively address risks and ensure human safety.

Our approach suggests that to be of a success the system of adaptive governance should be further refined. It is to be rooted in integration of climate adaptation policy and measures performed at international, national and local levels, while adaptation strategies, mechanisms, tools, monitoring and verification procedures over implementation be coordinated across geographies, levels and with stakeholders. Innovations in this package involve transformations in institutions, legal and socio-economic instruments, technologies, financing and changes in population behavior to reduce vulnerability to climate risks. Effective adaptation strongly relies on taking into account the specifics of the domestic environmental and socio-economic factors. Selection of adaptation options is a tricky task, as it requires multidisciplinary approaches and stronger links between natural and social sciences. Institutions should be flexible and maneuvering [12] under high climate uncertainty deriving from scenarios of global warming and variety of risks and surprises to society, depending on ecosystem change and socio-economic and geopolitical dynamics; climate institutions might be vulnerable to 'black swans', i.e. unpredictable events with unforeseen consequences. The overall quest relates to design of response and adaptation actions for implementation of global climate change regime.

Recent trends indicate at certain advances in global development of both domestic and international adaptation practices. Today the adaptation is launched by many countries and communities. About 84% of the parties to the UNFCCC elaborated their adaptation policy and measures; the number of such countries is constantly growing – by about 5% annually. Their adaptation policies are quite diverse, and include plans and strategies, domestic legislation, national- regional policy and measures, institutions, socio-economic and financial instruments, engineering tools and structural measures (dams, levies, construction requirements, territorial planning, relocation of settlements and business from areas under disaster risk, etc.). In some countries economic instruments applied suggest credits and subsidies for house construction reinforced against floods, incentives for adaptation of local production, support of small business and indigenous communities, insurance services, etc.

A number of serious gaps in adaptation is indicated worldwide, both in developed and developing countries. Among them, is inadequate funding for measures against risks of extreme events, particularly in developing countries. Today, international allocation of funds to climate adaptation in developing countries is about 10-18 times lower than their actual needs, and this divide is constantly growing. International public finance flows to developing countries in 2021 accounted for US$21 billion [2]. According to recent international estimates annual costs of adaptation in developing countries could increase up to US$ 215-387 billion per year during the decade 2021-2030 and up to $315-565 billion by 2050[13]. At the same time experts note that high level of funding cannot compensate for adaptation shortages. To be of success the system of adaptive governance needs to be wisely designed as many failures in response to climate risks are associated with mistakes in selecting governance options. For example, in North-South international aid to adaptation, the finance is among its key elements, but at the same time in many cases, the technology transfers and domestic capacity building is underestimated. Fragmentation of current domestic and international practices is among flaws of adaptation, while exchange of good practices is insufficient. The list of gaps in adaptation governance also include: 1) deficit in coordination between institutes, sectors and stakeholders; 2) problems with integration of adaptation mechanisms into territorial planning; 3) insufficient participation of local population in risk reduction and involvement of different stakeholders; 4) corruption related to resources transfer from the center to locales; 5) focus on short term projects versus sustainability within a long perspective, etc. Most of them refer to both developing and developed countries.

Adaptation to impacts of global climate change is becoming an important new area of climate international law and policy. Today, the *international regime on climate adaptation* is under formation within the 1992 UNFCCC and its 2015 Paris Agreement. The Paris Agreement establishes the long-term global goal to carry out measures and policies to "enhance adaptive capacity and resilience and reduce vulnerability, with a view to contributing to sustainable development" (Art. 7, c. 1). It describes adaptation as a global challenge "faced by all within local, subnational, national, regional and international dimensions, and a key component to the long-term global response to climate change to protect people, livelihoods and ecosystems". Adaptation measures take into consideration the individual characteristics of countries and regions, "vulnerable groups, communities and ecosystems, and should be based on and guided by the best available science and, as appropriate, traditional knowledge, knowledge of indigenous peoples and local knowledge systems" (Art. 7, c. 1, 2, 5).

Common international standards, norms and regulatory procedures had been introduced. For example, country-parties contribute to the implementation of their commitments under the global climate regime by regularly submitting to the UNFCCC secretariat their national communications according to the standard format of reporting on adaptation work undertaken and for follow-on verification. Adaptation section in national reports contains the following data: (1) assessment of risks and consequences of climate change for territories, industries, and populations; (2) policies; (3) strategies and programs; (4) measures, mechanisms, and instruments; (5) climate services for end-users; (6) research results; (7) implementation of plans, and related gaps; (8) international cooperation; (9) assistance to developing countries. For disaster prone regions the regulatory norms of the Paris agreement relating to climate risk reduction, damage prevention and exchange of competences are particularly relevant, including international provisions for early warning systems, emergency preparedness, rescue and evacuation, rehabilitation of affected territories, risk assessment and management.

The novel trend is in shifts from earlier declarative to concrete step-by-step approach in implementation of international adaptation regime. It is applied for the entire adaptation cycle – from (a) assessment of the core climate impacts and vulnerabilities of countries, to (b) domestic planning, (c) voluntary adaptation action, (d) monitoring and assessment of results, (e) exchange of good practices, including technology-engineering solutions, funding, capacity-building. In 2023, the *UAE Framework for Global Climate Resilience* was adopted at COP-28 (UEA, Sharm-el-Sheikh) [2]. For the first time, this program builds the multilateral adaptation system for realization of the Paris agreement *Global Goal on Adaptation* in order to jointly contribute to safety of world population, economic sectors, infrastructure, and ecosystems facing current and future adverse consequences of climate variability. The innovation is in clear norms for structuring the governing institutions, adaptation strategies, instruments and verification tools, enhancing transparency and compatibility of multiple domestic practices. Refining the system of international indicators and adaptation metrics to measure the progress in reaching global adaptation goals and to verify reporting of the parties is among its tasks. New adaptation funding mechanisms and instruments are to be developed in order to increase financial flows, and to provide direct and easier access to them by developing countries, including wider use of preferential finance and grants.

Importantly, particular time frames are set for this process. For example, by 2025 it is planned to finalize development of national adaptation plans, policies and measures with their

[2] UN FCCC. Decision -/CMA.5 Glasgow–Sharm-el-Sheikh work programme on the global goal on adaptation referred to in decision 7/CMA.3 https://unfccc.int/documents/636595

disaggregation across sectors, regions and communities; by 2027 - to enact international and national system of monitoring, assessment of climate risks and inventory of states/regions vulnerability to risks. Among major problems today is that about one third of the world territory is within the risk-prone zone because it has no access to systems of early warnings on disaster emergency, to climate information and services. It is planned to combine a network of multilateral, regional, national systems (with universal coverage by disaster early warnings, regular risk monitoring and assessment, climate services, Big Datat). It is suggested that their development by 2030 would serve as a basis for the UNFCCC plans to undertake the global assessment of implementation results of national adaptation plans with global inventory of domestic practices, and a follow-on refinements of the adaptive governance system.

II. Loss and Damage

Loss and damage (LD) attributed to impacts of climate change is among the core attributes in assessment of climate risks and possible adaptation measures. So far, there is no unified definition of LD. Current discourse on the issue centers either (a) on evaluation of harm (economic and non-economic [3]) from observed and expected climate change negative consequences and risks, or (b) on critical assessment of international North-South debate on legal procedures for its mitigation under the UNFCCC. Usually LD is understood as adverse effects of climate change that are not avoided through climate adaptation, or mitigation efforts. Loss is linked with irreversible harm, for instance through complete destruction in functioning of assets, infrastructure, sectors (for example, as a result of flooding from sea level rise in small island states). Damage refers to negative effects and costs associated with climate change impacts that could be quantified, and often could be dealt with involving repair and restoration, or compensation.

Still, there is a great deal of uncertainties and diversity in approaches regarding concepts, typology, methods for costs assessment, and structure of measures to deal with the problem; altogether, it sets barriers for dealing with climate LD. Existing estimates of LD and high current and future costs to address them vary significantly. For example, it is suggested that LD costs in vulnerable developing countries might account for $ 400 billion in 2030 and raise up to $ 1-2 trillion by 2050 [14]. Most countries worldwide are under risk of climate disasters, and LD costs vary across countries and regions depending on their vulnerability and exposure to different extreme weather and emergencies. Developing countries face higher risks due to their comparatively lower domestic capacity to mitigate disasters.

International regime formation to address climate LD [15] highlights three important features and new trends. *First*, the process of its dynamic North-South international dialogue over the last three decades resulted in the progress towards multilateral coordination of various approaches and stakes of its parties. It culminated in 2022 in historical decision to establish international financial mechanism for reduction of LD and related risks in most vulnerable developing countries. *Second*, its formation is marked by particular stages in designing its institutions and regulatory norms; it clearly demonstrates transition from perceptions to actions in coordination of joint efforts. *Third*, being rooted mostly within the UNFCCC climate regime, its main vector directs towards designing the global architecture for climate adaptation and addressing LD issues through tighter synergy between currently fragmented efforts of various international agencies at different levels.

The core of the LD multilateral problem has been rooted within the global South- North dialogue, and particularly, in interpretation of *compensation* and *liability* for climate LD. Climate aid to most vulnerable countries and financial compensation schemes for damage caused by historical GHG emissions from developed countries had been the red thread in long multilateral

[3] Economic LD is calculated on the basis of monetary value of damage to economic sectors, infrastructure, individual assets; non-economic LD is more difficult to evaluate as it is associated with non-monetary values like loss of life, health, territory, cultural heritage, biodiversity

debates. Climate justice, 'moral responsibility' and possible climate reparations for damage had been also a part of regular international narrative. Due to complexity of the problem with a great deal of conceptual uncertainties and controversies in North-South approaches to problem-solving, it took over three decades of active debates to reach the compromise through a joint agreement to institutionalize the LD issue.

Indeed, there is a diversity of parties' perceptions regarding options and tools for compensation of climate change damage for developing states. Enacting mechanisms for LD compensation had been the goal of the vulnerable least developed countries, while developed countries had been its opponents. As a result financial support and compensation were in foci of international discussion. Until recently within the climate diplomacy industrialized countries usually managed to block attempts of developing countries to negotiate financial aid for implementation of their domestic adaptation plans. The result has been in 'underfinancing' of global adaptation actions according to the last assessment of UNEP. Among the reasons had been also the existing gap in international legal framework for financing adaptation, as well as in the international legal norms for LD obligations and responsibilities of the countries. Despite recent progress in institutionalizing the funding arrangements, at the last moment of negotiations the developed countries succeeded in reaching a compromise by focusing the international finding discourse on 'cooperation and facilitation' rather than 'liability and compensation'.

A number of stages in International regime formation related to LD regulation and norms could be tracked. In fact, the LD issue entered the international policy agenda under the UNFCCC just from the start of climate negotiations in 1991, when the problem was initially raised by the *Alliance of Small Island States* (AOSIS) by proposing the creation of an international pool to compensate for LD from the sea level rise to the most vulnerable small islands and low-lying coastal developing states. Particularly dynamic this process became during the last decade. After a long period of general discourse on conceptual approaches to liability and compensation the LD reentered negotiations, and with the 2010 Cancun work-programme on LD concrete steps towards its institutional design were taken. In 2013 the *Warsaw International Mechanism* (WIM) for LD was enacted to serve as the lead international structure to coordinate international action towards LD risk management, to enhance knowledge from science and practice in order to develop mechanisms for support and capacity building in the most vulnerable states; it was focused on research, dialogue and knowledge exchange, rather than liability and compensation. In 2015, the important milestone has been the incorporation into the Paris agreement of special provisions to regulate international efforts to 'avert, minimize and address LD' (art.8). In 2019 the *Santiago Network for Loss and Damage* (SNLD) was mandated to focus particularly on procedures and technical aspects of international climate aid to developing countries and to define effective instruments for facilitating access to finance, information, best practices, technologies and capacity building.

Finally, the recent mutual compromise in negotiations suggests that the Paris agreement envisions the continuation of WIM, but explicitly outlines that involvement of the latter does not provide for any liability, or compensation. The inclusion of this clause was a condition on which developed countries, and particularly the USA, agreed to include a reference to LD into the international accord. As a result, a novel architecture for North-South cooperation within international system of climate adaptive governance is developing. Creation in 2022 of the new financial mechanism for support of adaptation in developing countries with its multilateral Fund on LD is important landmark in this process.

III. Multilateral Fund on Loss and Damage

Launch of international financial mechanism with its special multilateral *Fund for Loss and Damage, FLD* at COP 27 (Sharm-el-Sheikh, UAE) in 2022 is regarded as a breakthrough. It is based on joint multilateral agreement on funding to least developed and most vulnerable states to adverse climate change. Today the operationalisation of FDL is at the agenda, and the key issues include: 1) governance design; 2) recipients of finance; 3) donors and sources of funding; 4) principles and instruments for actual LD assessment; 5) fund's role in the system of international climate finance. Answers to these basic questions require further detailing and coordination between the parties involved in the regular UNFCCC process.

Governance and *operationalization* are the basic issues in the FLD performance. Currently, the decision–making is underway regarding its goals, activity, legal status, governance and institutional procedures, its structure, membership, funding sources, selection of recipients, norms for access to finance, financial instruments, monitoring, reporting and verification procedures, interaction with other international climate finance mechanisms. It is supposed to serve as an operational LD finance mechanism under the UNFCCC. At initial stage the World Bank is supposed to provide the administrative support, consulting and maintenance of its secretariat.

FLD Governing Board is the major organ for consensus decision-making and strategic planning. It consists of 26 members, including 12 from developed countries, 14 from developing states and regional groups, including 3 from each - Asia-Pacific, Africa, Latin America and Caribbean region; 2 each from developing small islands states, and from least developed countries; 1 from developing state - nonmember of the regional groups. The Board has 2 co-chairs – from developed and developing countries. The Secretariat serves as its working body and it is headed by the executive director of the Fund; regional departments are part of its structure.

Recipients eligible for funding are selected basing on the key goal of the fund – support for least developed countries vulnerable to extreme natural disasters and slow on-set processes. Funds are to be transferred to actions in LD reduction and for capacity building to prevent both economic and non-economic damage. They cover rehabilitation of affected areas and support to local population, to reconstruction and restoration of economic assets and infrastructure. International aid is provided to develop national adaptation plans and programs on LD reduction, or to assess the financial needs of the recipients to perform protection measures and develop national finance systems for LD compensation. Perspective direction of action eligible for funding - production of climate data and operational dissemination of climate services to end-users, support for relocation and mobility of people seriously affected by disasters.

Among its main finance instruments destined to the global South are grants and preferential loans. Application of additional financial products are currently discussed, such as guarantees, direct budget funding, politically motivated finance, shares, insurance, risk-sharing, performance-based programs. They are regarded as supplementary to national resources directed to LD reduction measures. Specifics in the national context is taken into account in decision-making on selecting the recipients and instruments applied: climate vulnerability indicators in combination with socio-economic and sustainability parameters are assessed in detail. FDL is developing specific norms for funds distribution, including assessment of potential recipient priorities based on risk indicators, LD indices, national capacity in adaptation, general level of international funding, estimate of costs for post-crisis rehabilitation and reconstruction, etc.

FLD puts is its special accent on procedures and instruments to ensure direct and simplified access of an applicant from a developing country to funding, and to lift administrative barriers for international finance. Funding support in emergency situations should reach its consumers before it's too late. It could be provided through national and regional branches, and on the basis of applications for comparatively small grants for local recipients. Proposed operational allocation of funds through rapid track and simplified procedures for evaluation of applications in case of emergencies is an innovation. It is combined with transparency principles for resource allocations, reporting and verification, avoiding excessive bureaucratic barriers in access to finance. Special institutional procedures are designed to ensure easier access to finance and implementation of aid-programs. National organ responsible for management and realization of actions supported by the Fund could be established in a recipient country. There is a choice of available options: (a) direct access via budget funding of national government, or partner organizations; (b) direct access via sub-national, national or regional organizations, or via partnerships with organs accredited with other international funds, for example, such as the Adaptation Fund, the Global Environmental

Facility (GEF), the Green Climate Fund; (c) international access through multilateral or bilateral agencies; (d) small grants for support of local adaptation projects, of indigenous communities, most vulnerable groups and settlements, including their rehabilitation after natural disaster

Sources of funding are among crucial issues. Resources of FLD are to be formed from a variety of sources, including donor states with their grants and preferential financing from governmental and private funders, as well as NGOs and different funds. Multilateral LD funding would be mobilized in addition to already functioning multilateral mechanisms of climate finance and international aid to sustainable development. Currently there is a variety of estimates of possibly mobilized adaptation funding. According to UNFCCC estimates by the end of 2023 at the start of FDL launch, several donor states announced their pledges on annual climate finance totaling to about $700 million (including, by the EU – €225 million, Italy – $200 million, Germany – $100 million, UAE – $100 million, with smaller funding from UK, USA, Japan). The effect of such financial mechanism for climate adaptation in developing countries would be tested in practice with the start of FDL performance. Among main concerns is how fast and effectively the operalization of its procedures and coordination of donors-recipients approaches would be undertaken. However, initial estimates indicate that expected funding might be quite modest versus possible annual costs of climate disasters mitigation in developing countries in mid-term perspective. The important question about methods and norms for assessment of actual LD in each recipient county-case, including economic and non-economic damage still remains open.

TOWARD RISK FORMALISM. THE SCORE MATCHING METHOD IN A GROUP CHOICE PROBLEM

a.bochkov@vniias.ru

Abstract

The task of coordinating expert assessments inevitably arises in the expert construction of integral indicators of objective judging in sports, analysis of the state and risks of functioning of social, economic, environmental, transportation systems and for many other subject areas of human activity. A decision-maker, as a rule, sets a criterion by which an object is evaluated, and an expert defines a set of comparable objects according to this criterion and evaluates each object, ranking them in descending (ascending) order of one or another quality. It is assumed that the expert has his own opinion that does not diverge from the generally accepted one and is not built only on the basis of measurable data. This opinion is based on his/her personal experience and knowledge gained in the process of work. As a result, there is often a situation when the transitivity of expert evaluations is violated. The proposed procedures for finding an integral indicator can be used in the tasks of decision-making, harmonization of expert assessments of the state of objects, construction of environmental and social indicators, as well as quality indicators, such as the integral indicator of the quality of life, the index of the quality of the transport system, the index of human development, etc. The methods of matrix theory are applied. The methods of matrix theory, graph theory and combinatorics are applied. The presented algorithm differs from existing methods in that it measures the contribution of the total error of experts to the collective measure of their consistency. The method under discussion offers a solution for decision makers in the so-called group selection problem (which means the task of analyzing and aggregating heterogeneous information about the preferences of compared objects into a single "group" preference) of critical objects that require increased attention of the security service and expenditure of resources of the state and the owner of the system to ensure their safety, security and sustainability of operation.

Keywords: expert evaluations, consistency, integral evaluation, group choice problem, permutations

I. Introduction

The method of recovering a consistent solution in expert ranking of objects involves the use of various techniques and approaches. One approach is to extend the use of Kendall's concordance coefficient (W) to incomplete rankings, allowing for the inclusion of objects that are not easily compared with others [1]. Another approach is to reconstruct expert preference functions using available data and expert judgment, which can be achieved using machine learning and matching techniques [2]. Decision analysis techniques can also be used to systematically analyze complex problems and improve the objectivity of remediation decisions by quantifying expert opinions and prioritizing remediation activities based on several criteria [3]. In addition, the rank analysis method can be applied to calculate the ranking of managed objects by replacing ordinal rankings with effective rankings that take into account the degree of difference in the estimated values [4]. Finally, decision making using fuzzy and fuzzy preference relations can be improved by introducing the concepts of additive consistency and group consensus analysis [5].

The following method is designed to find the most consistent solution in the task of ranking objects by means of expert evaluations. Such tasks are not uncommon in various fields of activity, where it is necessary to analyze several available alternatives and decide on their relative importance. As a rule, each of the experts involved in the evaluation has its own evaluation scales (most often irregular, since the experts have different experience and knowledge). Linking disparate opinions into one is an extremely important task for the decision maker (LPR).

The main obstacle to combining different opinions into one is the need for consistent assessments. The requirement for consistency in expert judgment is that the experts involved in the evaluation process make consistent and coherent assessments of the issue or subject under study. This means that experts must adhere to the same evaluation criteria and methods to avoid contradictory or inconsistent results.

Consistency of expert assessments is important to ensure the objectivity and reliability of the assessment results. Inconsistent assessments can lead to distorted conclusions and incorrect decisions based on these assessments. This fact clearly reflects the so-called Condorcet paradox.

The Condorcet paradox is a situation in which uncertainty or contradiction in preference determination arises in group preference selection using a voting method. This paradox was discovered by the French mathematician and philosopher Marquis de Condorcet in the 18th century.

The essence of the paradox is that it is possible that, given three or more alternatives to choose from, there is no voting method that satisfies all the basic principles of democracy at the same time:

- transitivity (if A is preferable to B and B is preferable to C, then A is preferable to C),
- independence from alternatives (a change in preferences for alternatives should not affect the voting result),
- absence of a dictator (the decision is made collectively, not by one person).

Condorcet's paradox emphasizes the complexity of group choice and shows that even the most democratic voting methods can lead to imperfect or inconsistent results in certain situations.

Condorcet's paradox of preference conflict in social choice has been studied by scholars and scientists for more than 200 years [6]. Various mechanisms have been proposed to resolve this paradox, including the use of rules in coordination games [7]. To understand the solution to Condorcet's paradox, strategic models of majority bargaining have also been analyzed [8]. It was found that in these models, there exists a stationary perfect equilibrium in the subgame that ensures agreement within a finite expected time [9]. In addition, mixed and consistent perfect equilibria in subgames have been found in the simplest Condorcet cycle, leading to immediate agreement in some scenarios [10]. These studies provide insights to resolve the Condorcet paradox and shed light on the factors affecting collective decision making.

Various methods such as consistency analysis method, Delphi method, expert judgment aggregation method and others can be used to ensure consistency of expert judgments. These methods help to identify discrepancies between expert assessments and make adjustments to achieve consistency.

There are many methods for assessing the consistency of expert judgment. The most common ones are:

1. Kendall's W coefficient of concordance: This method is used to measure the degree of consistency between multiple experts when evaluating the same item. It takes into account not only the consistency between pairs of experts, but also the average consistency between all experts.
2. Pearson's correlation coefficient (Pearson's r): This method is used to measure the degree of linear relationship between the scores of different experts. The closer the correlation coefficient is to 1, the higher the level of consistency.
3. Fleiss' Kappa consistency index (Fleiss' Kappa): This method is used to assess the degree of consistency between multiple experts when classifying objects into categories. It takes into account the random agreement between experts.
4. Consistency Ratio (C.R. - Consistency Ratio) in Thomas Saaty's method of hierarchy

analysis. This indicator allows assessing the degree of consistency between pairs of compared alternatives and identifying possible errors or contradictions in the experts' assessments.

The choice of method depends on the problem to be solved. The methods allow identifying inconsistencies in the estimates, but they do not offer to correct these inconsistencies by asking experts to refine their estimates repeatedly. Sometimes such a process is looped and the LPR is forced to make a decision at his/her own risk.

In 1951, C. Arrow formulated [11] the theorem "On the Impossibility of Collective Choice within the Ordinalist Method", mathematically generalizing Condorcet's paradox [12]. The theorem states that within the framework of this approach there is no method of combining individual preferences for three or more alternatives that would satisfy some quite fair conditions (axioms of choice) and would always give a logically consistent result.

II. Problem statement

The proposed method not only states the existing inconsistency in the experts' assessments, but also allows obtaining an optimal solution for the available assessments and the alternatives under consideration, "restoring" their correct ordering. The original author's algorithm for processing expert preferences in a collective choice problem based on the concept of the total "error" of experts and measuring their contribution to the collective measure of their consistency is presented in [13]. The authors called it the Pit Finding Method (PF-Method).

Let us recall the problem formulation from [13].

Considered N comparison objects $0_1, \dots, 0_n, \dots, 0_N$ whose indices are the first N members of the natural series $\langle 1, \dots, n, \dots, N \rangle$ - correspond to the order of submission of objects for examination (initial order). The examination of objects involves M equal experts $\mathrm{E}_1, \dots, \mathrm{E}_m, \dots, \mathrm{E}_M$. Each of the experts E_m has its own idea about the order of objects placement $g_m = \langle g_{m,1}, \dots, g_{m,n}, \dots, g_{m,N} \rangle$. The indices of which increase as some quality of objects decreases from the point of view of this expert. That is, the value $g_{m,1}$ corresponds to the index of the object O_{k_1}participating in the examination with the maximum evaluated quality in the expert's opinion E_m, a $g_{m,N}$ - the worst object with the assessed quality with the index of 0_{k_N}:

$$g_{m,n} = \begin{pmatrix} g_{1,1} & \cdots & g_{1,N} \\ \cdots & \ddots & \cdots \\ g_{M,1} & \cdots & g_{M,N} \end{pmatrix}.$$

Thus g_m - is a permutation of object ratings whose argument is the initial order: $g_m = \begin{pmatrix} 1 & \dots & n & \dots & N \\ g_{m,1} & \cdots & g_{m,n} & \cdots & g_{m,N} \end{pmatrix}$. Places $p_m = \langle p_{m,1}, \dots, p_{m,k}, \dots, p_{m,N} \rangle$ by values inverse to permutations of object ratings $g_m (p_m = g_m^{-1})$ are permutations of object indices with argument $E_{\text{ПИО}}$:

$$p_{m,n} = \begin{pmatrix} p_{1,1} = g_{1,1}^{-1} & \cdots & p_{1,N} = g_{1,N}^{-1} \\ \cdots & \ddots & \cdots \\ p_{M,1} = g_{M,N}^{-1} & \cdots & p_{M,N} = g_{M,N}^{-1} \end{pmatrix}.$$

It is necessary to find the compression of all private ratings of permutations of object ratings $g_m (m = 1, \dots, M)$ in the form of permutation of object ratings $g_m^* = \langle g_1^*, \dots, g_N^* \rangle$which would minimize the total inconsistency of expert evaluations $g_{m,n} \to g_m^*$ (on the basis of equality of all participants of the expertise), measured in inversions of transitions from $g_{m,n}$ к g_m^*i.e.

$$K^* = \min K(g) = \min_{g_m} \left(\sum_{m=1}^{M} K_m(\langle g_1, \dots, g_N \rangle) \right),$$

where $K_m(\langle g_1, \dots, g_N \rangle)$ - is the sum of inversions in the estimations $m$of -th expert, K^*- is the marginal measure of disagreement between the experts' opinions.

III. Algorithm description

Finding an optimum in permutations of object ratings is equivalent to finding a permutation of an object index p^*: $p^* = \langle p_1^*, \dots, p_N^* \rangle$, since $K(g_m^*) = K(p_m^*)$where p^*=$(g^*)^{-1}$ (the lengths of the back paths ($E \rightarrow g$) coincide with the forward paths ($p = g^{-1} \rightarrow E$) at any g) (Table 1).

M	$p_M(g)$	p_{M,g_1}	...	p_{M,g_k}	...	p_{M,g_N}	$B_M(p_M(g))$	$B_{M,1}$	...	$B_{M,k}$	...	$B_{M,N}$	$K_M(g) = \sum_{k=1}^{N} B_{M,k}$
													$K(g) = \sum_{m=1}^{M} K_m(g)$

After the experts have expressed their opinions, we assume that the order of submitting objects for examination corresponds to their correct ranking. Then, when pairwise comparisons of all experts' evaluations are made, the evaluations for the i-th object should be "better" from the point of view of its quality than the assessments of the -th object. $i + 1$of the -th object. If this assumption is violated, a "penalty" is fixed for this compared pair and the total "experts' error" is increased by one. If the total "experts' error" turns out to be higher than some specified value (e.g., $\frac{N}{2}$), a contradiction arises, reflecting the inconsistency of experts' opinions when comparing this pair. Obviously, the lower is the set value of the total "error", the more stringent are the requirements to the consistency of experts' opinions.

For N for the objects, it is necessary to perform $N \cdot (N-1)$ pairwise comparisons. As a result of all comparisons, we obtain a square matrix of dimensionality $N \times N$in which the main diagonal consists of zeros (object's evaluations are compared in pairs with its own evaluations), and the matrix elements represent the corresponding total errors of experts, obtained as a result of the above described pairwise comparisons.

Then we rearrange the columns and rows of the obtained matrix in pairs, trying to move the maximum number of matrix elements, whose values are greater than the specified value of the total error, below the main diagonal. At such permutations the order of columns of the initial error matrix will change. The final order of columns will reflect the maximally consistent decision on the ranking of the compared objects. If such a solution is not the only one, it is necessary to calculate the value of the inconsistency criterion for all obtained solutions $K(g)$taking the obtained solution as the initial order of objects. The solution that has received the minimum value $K(g)$will be the final one.

Let us illustrate the work of the method on numerical examples.

IV. Case of study

Let seven experts $\mathrm{E}_m (m = 1,2,\ldots,7)$ compare 4 alternatives on some basis $\mathrm{O}_n (n = 1,\ldots,4)$. Let also let the initial order of the alternatives being compared be given by the mapping $\langle 1\ 2\ 3\ 4 \rangle \leftrightarrow \langle \mathrm{O}_1\ \mathrm{O}_2\ \mathrm{O}_3\ \mathrm{O}_4 \rangle$.

For a given set of evaluations of the alternatives being compared $\langle 1\ 2\ 3\ 4 \rangle$ it is necessary to find such a group $\langle k_1 \ldots k_4 \rangle$for which there is no possibility to improve the optimality criterion $K(g^*)$. The total number of consecutive inversions of each expert's evaluations is taken as the optimality criterion $K_m(g^*)$, restoring the current working order to the original one. In other words, it is necessary to find such a group for which $K(g^*) \rightarrow K_{\min}$.

	1	2	3	4
	O_1	O_2	O_3	O_4
E_1	1	4	2	3
E_2	2	3	1	4
E_3	3	2	1	4
E_4	4	2	3	1
E_5	1	4	3	2
E_6	2	4	1	3
E_7	2	1	4	3

	1	2	3	4	Inversions				$K_m(g^*)$
	O_1	O_2	O_3	O_4	1→1	2→2	3→3	4→4	
E_1	1	4	2	3	0	1	1	0	2
E_2	2	3	1	4	2	0	0	0	2
E_3	3	2	1	4	2	1	0	0	3
E_4	4	2	3	1	3	1	1	0	5
E_5	1	4	3	2	0	2	1	0	3
E_6	2	4	1	3	2	0	1	0	3
E_7	2	1	4	3	1	0	1	0	2
								Optimality criterion $K(g^*)$:	20

Fig. 1 shows all pairwise comparisons of object evaluations and the scheme of forming the matrix of "errors". Bringing the matrix of pairwise comparisons of evaluations assigned to alternatives by experts to the form in which the upper triangular matrix contains no contradictions, we obtain the desired solution ⟨3 1 4 2⟩ (Fig. 2).

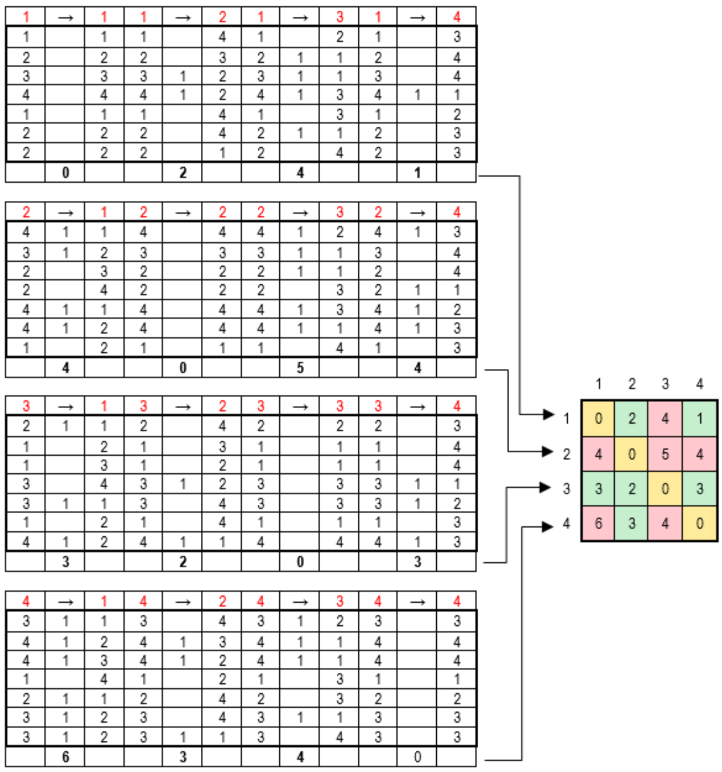

Figure 1: *Scheme of formation of the "errors" matrix*

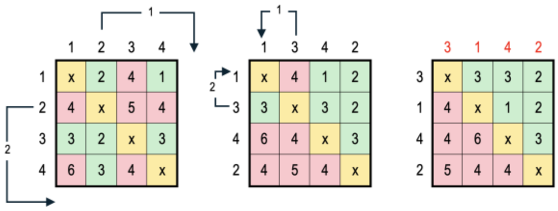

Figure 2: *Elementary transformations of the "error" matrix*

Since there are no contradictions in the upper triangular matrix, this solution is the only and non-improvable one. Let us check its compliance with the optimality criterion:

	3	1	4	2	Inversions				$K_m(g^*)$
	O_1	O_2	O_3	O_4	1→1	2→2	3→3	4→4	
E_1	2	1	3	4	1	0	0	0	1
E_2	1	2	4	3	0	0	1	0	2
E_3	1	3	4	2	0	2	0	0	2
E_4	3	4	1	2	2	2	0	0	4
E_5	3	1	2	4	1	1	0	0	2
E_6	1	2	3	4	0	0	0	0	0
E_7	4	2	3	1	3	1	1	0	5
							Optimality criterion $K'(g^*)$:		15

As can be seen from the table, the expert E_6 "guessed" the optimal solution, since. $K_6(g^*) = 0$. Experts E_1 и E_2 made only 1 error each, E_3 и E_5 - 2 errors each, and E_4 и E_7 - too many errors. The optimality criterion is *met* $K'(g^*) < K(g^*)$.

By reconstructing the $g^* = \begin{pmatrix} 1 & 2 & 3 & 4 \\ 3 & 1 & 4 & 2 \end{pmatrix}$ the optimal sequence as $p^* = (g^*)^{-1}$ we obtain the desired locations $p^*(E) = \langle 2, 4, 1, 3 \rangle$.

V. Concluding remarks

The situation arising after permutations in the "errors" matrix will not always be as shown in the demo example. The problem of finding the optimal order of the evaluated objects may have several possible solutions. In this case, the best solution is determined by calculating the optimality criterion for all obtained solutions and selecting the solution that has the smallest value of this criterion. In most of the cases tested by the authors, the solution resulted in a global optimum, which favorably distinguishes the method from Schulze's method, for example. In addition, unlike the Schulze method, the PF-method is computationally much simpler and clearer.

Further development of this method implies its application in ranking definitions that allow equality of scores of the compared objects when determining the weight coefficients of the compared objects (similar to pairwise comparisons in the method of hierarchy analysis [14] and solving problems of fusion of heterogeneous scales [15, 16]).

Abstract

In this paper, procedures for modeling rare events, which include power and energy shortages, are considered when analyzing the balance reliability of electric power systems using simulation methods. The primary goal is to investigate the use of iterative methods to form a sequence of nested probability subspaces with decreasing probability. Implementations of the subspace method are considered. A modification of the entropy method is proposed that involves a smooth adaptation of the indicator functions. The discussed procedures undergo a comparative analysis. The main disadvantage of the considered methods is their efficiency, which depends on the proper specification of parametric constants. The methods to improve the accuracy and convergence of iterative procedures are outlined.

Keywords: Monte Carlo simulation, power system reliability, simulation of rare events, cross-entropy method, probabilistic evaluation

I. Introduction

The main task of analyzing the reliability of an electric power system (EPS) is to assess the probabilistic indicators (probability, frequency, mathematical expectation, etc.) of power deficit (PD) in the EPS, the presence of which is considered a violation of the normal functioning of the EPS (failure) [1–3]. All technical systems, including EPS, exhibit a low probability of failure (a fraction of a percent) [4–5]. A technical system's reliability analysis is associated with the modeling and analysis of failure events. In this case, as a rule, failure occurs with an infinitely large combination of external events. Thus, in an EPS with two load nodes and a fixed maximum power of electric stations, a power deficit can manifest itself with an unacceptably large increase in the load of either the first, second, or both nodes. In this case, the excess of the total load over generation is continuous and hence has an infinitely uncertain value in implementation. The number of load and generation nodes in real EPS design circuits is measured in thousands. As a result, the probability of failure increases many times over, and identifying the most significant combinations of events leading to system failure becomes difficult.

The main mathematical apparatus for analyzing the reliability of EPS is currently the methods of statistical tests, and in particular the Monte Carlo method (MCM) [6–10]. These methods make it possible to model systems with complex functional relationships that cannot be described analytically, including taking into account the stochastic uncertainty associated with supply, demand, and the capacity of intersystem connections. The main drawback of the MCM is known: to ensure the required accuracy of the results, a sufficiently large number of tests is required, since N is inversely proportional to the probability of the simulated events. In particular, when modeling an event with a probability of 10-3 and a modeling error of 1%, at least 106 statistical tests are required [11]. When analyzing the balance reliability of real EPS, the most significant are multiple failures (simultaneous failure of two power transmission lines, simultaneous failure of a power line and a power unit, failure of a power unit during peak loads, etc.), since single failures of EPS electrical equipment, as a rule, do not lead to limitations on power consumption. EPS are designed and constructed taking into account criterion N-1, in which a single failure of any element of the EPS should not lead to failure of the power supply process to consumers [12–14]. The probability of multiple independent failures is equal to the product of the failure probabilities of the failed elements. As a result, the probability of multiple failures takes values of 10-5–10-7. At the same time, to identify, model, and analyze post-emergency states of EPS using the MCM method, the number of tests is required to be at least 107. With a smaller number of tests, the identification of such rare events becomes unlikely, which leads to a significant error in the resulting reliability indicators [14].

Given that each test necessitates the execution of optimization calculations (optimal flow distribution), the reliability analysis of EPS will require several hours of computer time. Note that most general problems, such as choosing the optimal configuration of the electrical network during its development, involve the calculation of reliability indicators. Hence, the duration of calculating the reliability of the EPS development option as a separate calculation block is limited in time. The modern power system requires increasingly complex detail and expansion of the factors taken into account, which non-linearly increases the complexity of the task of assessing the reliability of the EPS. Taken together, this leads to the inexpediency, and sometimes even impossibility, of using a standard MCM to assess the reliability indicators of a power system. Modifications of the MCM are required, aimed at increasing the computational efficiency of statistical methods.

One of the ways to solve the problem of performing a large number of relatively similar calculations associated with modeling rare (with a failure probability of less than 10-5) events in a multidimensional probabilistic space is the idea of parallel computing. The technology for simultaneous use of several computers (or processors) has been actively developing over the past 30 years [15–17]. Parallel calculations certainly reduce the computational load of the MCM. However, the relationship between the number of parallel computing resources and computation time is similar to a linear function [17]. Hence, when modeling rare events, the positive effect of parallelization of calculations becomes less obvious. Another direction is the use of pattern methods, metamodels, artificial immunity, artificial neural networks, least-squares support vector machines [18–21], etc. These methods have also demonstrated a reduction in the MCM method's computational load. However, as a rule, for reliability evaluation tasks, they have not been tested, are focused on a certain class of problems, are often ineffective, and do not provide the required accuracy and reliability of identifying events with a probability of less than 10-4, which is typical for real energy systems. Hence, the problem of identifying rare events remains relevant. Iterative methods associated with the transformation of analyzed spaces, functions of probability distributions of random variables, and criterion functions are more universal in nature. The most common methods in this class are subspace and significant sampling methods [22–25], as well as cross-entropy methods [26–28].

This paper proposes and analyzes new procedures for determining the probabilistic parameters of rare events based on nested set methods, including mono and polycenters for forming an intermediate sample of significant events, as well as a modification of the cross-entropy method. The models and methods used in this study are described in Section III and IV, after Section II, where the mathematical formulation of rare event simulation is highlighted. Section V presents an example case study, and the results are analyzed to address the objectives of the work. In Section VI, conclusions are drawn.

II. Mathematical formulation of Power Deficit as a rare event

Let $\boldsymbol{x} \in \mathbb{R}^{\boldsymbol{m}}$be a random vector that combines all probabilistic input variables, $L_i, G_i,$ etc. In the simplest case, when only available generation and load are taken into account and random states of system elements, ambient temperature, etc. are not taken into account, $\boldsymbol{x} = \{L_i, G_i,\ i = 1, \dots, n\}$, where i –where is the number of the electrical network node. In order to focus attention on the mechanisms for identifying rare events associated with failures of EPS operation, the set of random, probabilistically determined quantities in this work is limited only by the load and available generation.

The deficiency of the system is determined by the difference $D_\Sigma = L_\Sigma - G_\Sigma = \sum L_i - \sum G_i$, $L_\Sigma > G_\Sigma$. It can be estimated, for example, using the system power deficit (PD) function, $S = G_\Sigma - L_\Sigma$ or (taking into account the capacity of the electrical network) $S = \min(G_i - L_i, \forall i)$. When $\{L_i, G_i\}$ is independent, it often makes sense to consider a generalized random variable - the available generating capacity of a node, $r_i = G_i - L_i$. Its mean and variance: $\mu_{r_i} = \mu_{G_i} - \mu_{L_i}$; $\sigma_{r_i}^2 = \sigma_{G_i}^2 + \sigma_{L_i}^2$. As a result, the number of control stochastic variables is reduced to the number of nodes in the electrical network. In this case, $D_\Sigma = -r_\Sigma = -\sum r_i$, $r_\Sigma < 0$.

In general, when analyzing local PDs, it is necessary to take into account the laws of power distribution in the electrical network. In this case, each node is characterized by the export $u_i, i = 1, \dots, n$ or import (-u_i) of power, determined by the dispatch control of the EPS and depending on the available power of the nodes $u_i = u_i(\boldsymbol{r})$. In this case, the local PD $D_i = u_i - r_i = u_i - G_i + L_i$; $D_i > 0$. With local PD, the system PD is fixed if at least one of the nodes has a local PD $D_\Sigma = \sum D_i$. To more accurately account for the scarcity of EPS, it is necessary to take into account active power losses in the network, which are determined by the distribution of power flows $\boldsymbol{z} = \{z_j, j = 1, \dots, m\}$ in the elements of the electrical network and are nonlinear in nature. Taking into account power losses is associated with the appearance of an additional condition $\pi_\Sigma = \sum u_i$. In this case, $D_\Sigma = L_\Sigma - G_\Sigma + \pi_\Sigma$, $\mathcal{D}_\Sigma \geq 0$.

Vector $\boldsymbol{z}$ is determined by solving the problem of optimal distribution of load power between power sources. In the simplest case, acceptable in reliability assessment problems, we can consider $\boldsymbol{z} = C\boldsymbol{u}$ where C is the flow distribution matrix [7]. As a result, it can be noted that the PD in an EES represents a complex (often determined algorithmically) functional dependence on a set of control variables, usually of a random nature.

The system failure state is fixed if some criterion function $\psi(\boldsymbol{x})$ specified on the set of control variables exceeds its inherent threshold value, $\psi(\boldsymbol{x}) < \psi_{lim}$. In practice as shown in Fig. 1, to identify failures, a function with a zero threshold is more often used, $S(\boldsymbol{x}) = \psi(\boldsymbol{x}) - \psi_{lim}$, which takes a negative value when the system fails, $S(\boldsymbol{x}) < 0$. In this case, the region of system states characterized as "failure":

$$H := \{\boldsymbol{x} \in \mathbb{R}^{\boldsymbol{m}} : S(\boldsymbol{x}) < 0\}. \tag{1}$$

If we consider the presence of PD in the EPS as a failure, then the criterion function has the form:

$$S(\boldsymbol{r}) = \min\left(\sum r_i - \pi_\Sigma;\ r_i - u_i(\boldsymbol{r}), \forall i\right).$$

The criterion function corresponds to the indicator function:

$$J(\boldsymbol{x}) = \begin{cases} 1, & S(\boldsymbol{x}) < 0; \\ 0, & S(\boldsymbol{x}) \geq 0, \end{cases}$$

which allows you to express many logical constructions in analytical form. In particular, the probability $\mathbb{P}_H$ of a failure state (the presence of a power deficit in the EPS) can be defined as the mean of the indicator function $J(\boldsymbol{x})$, which in state $\boldsymbol{x}$ takes the value 1 in the presence of a failure in the EPS and 0 in its absence:

$$\mathbb{P}_H = \int J(\boldsymbol{x})\, f(\boldsymbol{x}) d\boldsymbol{x}, \tag{2}$$

where $f(\boldsymbol{x})$ – is the probability density function (PDF) of the multidimensional random variable $\boldsymbol{x}$ that determines the event under consideration. For a given PDF $f(\boldsymbol{x})$, the probability of a rare event occurring is determined by the region H, that satisfies the criterion $S(\boldsymbol{x}) < 0$.

$$\mathbb{P}_H = \int_{S(\boldsymbol{x})<0} f(\boldsymbol{x}) d\boldsymbol{x}.$$

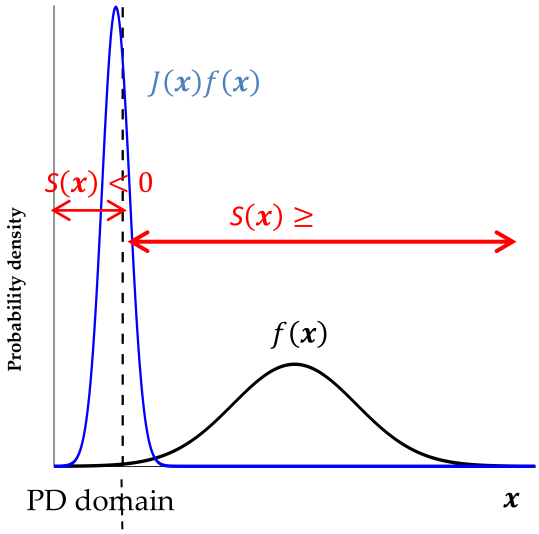

Figure 1: *Derivation of distorted probability distribution*

The PDF $f(\boldsymbol{x})$ of a random vector $\boldsymbol{x}$ of system states is almost impossible to represent in the form of an analytical expression, since it is the result of the convolution of a large number of system parameters of different types, with different parameters (loads, generations, binary variables that determine the state of system elements, solar radiation, wind speed, etc.). That is why the main method of analyzing the reliability of EPS at present is the simulation method (MCM), which allows, through repeated tests and their statistical processing, to obtain a fairly accurate estimate of the required values. In this case, as initial data, as a rule, the parameters of marginal distributions of initial RVs are set (for example, the load of node i of an EPS is described by a normal (Gaussian) distribution with a mathematical expectation μ_i and a standard deviation (STD) σ_i, $L_i \sim N(x, \mu_i, \sigma_i)$.

III. State subspace method

The performance of the MCM can be improved by applying variance reduction techniques such as significance sampling. The main idea of this group of methods is the formation of a sequence of subsets, $H_1 \supset H_2 \supset \cdots \supset H_m = H$ of the system state space, where each subsequent subspace increases the probability of identifying rare events and is determined on the basis of the previous one, forming a sequence of the Markov chain. In this case, the probability of the occurrence of a rare event can be written as follows:

$$\mathbb{P}_H = \Pr\left(H = \bigcap_{j=1}^{m} H_j \right) = \prod_{j=1}^{m} \Pr\left(H_j \middle| H_{j-1}\right).$$

Each subsequent subset is chosen so that the probability of the conditional event $\Pr\left(H_j \middle| H_{j-1}\right)$ would be large enough. As a result, a small probability is represented as a product of relatively large probabilities [23–25]. One of the ways to form $\left(H_j \middle| H_{j-1}\right)$ is to select a given share p_0 of the most significant events $X_b^j = \left(\boldsymbol{x}_1^j, \boldsymbol{x}_2^j, \dots, \boldsymbol{x}_k^j\right)$, where $k = p_0 N$; $N-$ is the sample size. The index b characterizes the maximum level of the criterion function $\psi(\boldsymbol{x})$ for the set X_b^{j-1}. The significance of events is determined by the value of $\psi(\boldsymbol{x})$ – the smaller $\psi(\boldsymbol{x})$, the greater the significance of $\boldsymbol{x}$ (for $\psi(\boldsymbol{x}_i, i = 1,\dots k) < 0$, the entire area X_b^j consists of "significant" (deficit states of the EPS)). Significance differentiation determines the mechanism of formation of the set X_b^j. The complete sample H_{j-1} obtained from the data of step $j-1$ is ordered in ascending order $\psi(\boldsymbol{x})$: $\psi(\boldsymbol{x}_1) \leq \cdots \leq \psi(\boldsymbol{x}_N)$. The first $p_0 N$ events ($p_0 \cdot 100$ percentile of the function ψ(x)) determine the set X_b^j and the maximum value of the criterion function corresponding to it, $b_j = max(\psi(\boldsymbol{x}), \boldsymbol{x} \in X_b^j)$, which, in turn, is the basis for the formation of a new set $H_j = \{\boldsymbol{x}: \psi(\boldsymbol{x}) < b_j\}$. In this case, the value p_0 can be considered as the probability of the conditional event $\Pr(H_j | H_{j-1}) = p_0$.

The presented stage-by-stage process of formation of a set of rare events is characterized by a positive value $b_j > 0$ at all intermediate stages. This means that the set X_b^j contains both failure events, $\psi(\boldsymbol{x}) < 0$, and non-failure events $\psi(\boldsymbol{x}) > 0$, that is, the principle of selecting events is to exclude less significant events and expand the region of more significant events , $b_j < b_{j-1}$. Initially, $b_0 = \infty$, which means that all system states generated on the basis of marginal PDF belong to the analysis zone. However, at subsequent stages, when generating the analyzed set of pseudo-random states of the system, a restriction is introduced: $\psi(\boldsymbol{x}) < b_{j-1}$. As a rule, this is realized by replacing the PDF parameters of random variables with some new calculated values.

At the last stage $b_j < 0$. This means that all events in the truncated set with p_0 are failures. But failures can also be events that do not fall into the region determined by the percentile, $b_j < \psi(\boldsymbol{x}) < 0$. Here, the conditional probability is determined according to the relation: $Pr(H_m | H_{m-1}) = N(\psi(\boldsymbol{x}) < 0)/N$, where $N(\psi(\boldsymbol{x}) < 0) -$ is the number of sample elements of size N satisfying the requirement $\psi(\boldsymbol{x}) < 0$.

Depending on the algorithm, the total sample size $N^{(j)}$ at intermediate stages may differ from the specified N, however, the selection principle is preserved - only the p_0 −part of the set of system states formed for analysis is accepted for further consideration.

A. Monocenter for the formation of an intermediate sample

A relatively small set of X_b^{j-1} is only the basis for the formation of H_j. Its elements are determined according to the type and parameters of the pseudo-random number generation distribution function in step $j-1$. At stage j , these should be different parameters, with a greater degree of identification of a rare event. One of the possible options for the formation of a new sample is proposed to generate pseudo-random numbers distributed according to a normal distribution with mean $\boldsymbol{\mu}^j = \mathbb{E}(\boldsymbol{x}_1^{j-1}, \boldsymbol{x}_2^{j-1}, \dots, \boldsymbol{x}_k^{j-1})$ and variance $\boldsymbol{D}^j = \mathbb{D}(\boldsymbol{x}_1^{j-1}, \boldsymbol{x}_2^{j-1}, \dots, \boldsymbol{x}_k^{j-1})$. At the first stage, as $\boldsymbol{\mu}^{(1)}, \boldsymbol{D}^{(1)}$ the mean and variances of the considered set of initial random variables are taken. Since the vector with parameters $(\boldsymbol{\mu}^j, \boldsymbol{D}^j)$ is the best representative of the region X^j, it is reasonable to consider this vector as the center of the region H_j.

The new set of pseudo-random vectors generated at stage j with center $(\boldsymbol{\mu}^j, \boldsymbol{D}^j)$, in the general case, contains points that do not belong to H_j according to the criterion $H_j \subset H_{j-1}$, that is, do not satisfy the condition $\psi(\boldsymbol{x}) < b_{j-1}$. The solution to this problem is either the addition of the resulting set to N elements that satisfy the condition $\psi(\boldsymbol{x}) < b_{j-1}$, or a simple removal of unsatisfactory system states. In the latter case, the sample is reduced from N to N_j elements, but all elements of the remaining set belong to H_j. It should be noted that the number of elements to be removed is, as a rule, relatively small, and the reduction of the analyzed set has little effect on the statistical estimates of the desired parameters (in particular, on the probability and mean of PD).

Calculations show that the choice of $(\boldsymbol{\mu}^j, \boldsymbol{D}^j)$ as the center of formation of the set F_j leads to some overestimation of the probability of a rare event in the region of very low probabilities (order: 10-6 in relation to 10-7). More accurate is the choice of the center at the point $\boldsymbol{x}^{*j}$, corresponding to the maximum value at stage $j-1$ criterion function, $\psi(\boldsymbol{x}^{*j}) = b_{j-1}$. Here, it is a priori assumed that at least half of the new generation of system states will not satisfy the condition $\psi(\boldsymbol{x}) < b_j$, but this increases the probability of taking into account those states that do not fall into the statistical sample with the center $(\boldsymbol{\mu}^j, \boldsymbol{D}^j)$. An increase in the proportion of deleted events is inextricably linked with the requirement to increase the sample size N. The shift of the center $(\boldsymbol{\mu}^{*j} = \boldsymbol{x}^{*j-1}, \boldsymbol{D}^{*j})$ of the sample relative to the MO leads to the need to correct the variance $\boldsymbol{D}^{*j} = \boldsymbol{D}^j + |\boldsymbol{x}^{*j-1} - \boldsymbol{\mu}^j|^2$.

B. Gaussian distribution- centered method

The monocentric approach assumes the concentration of the sample around some center, for example, according to a normal (Gaussian) distribution with mean at the center of the sample. However, the principle of selecting a peripheral region according to the probability p_0 and the asymmetry of the region of a rare event (the greater the load, the greater the PD) casts doubt on the validity of the Gaussian distribution at intermediate stages. Logically more justified here is a probability distribution, unknown in type, but represented by a set of (reference) points defined at the previous stage $C_{j-1} = (\boldsymbol{x}_1^{j-1}, \boldsymbol{x}_2^{j-1}, \ldots, \boldsymbol{x}_k^{j-1})$. Statistical modeling of this distribution is possible by representing the set H_j as a union of subsets centered at the reference points $H_j = \cup H_{js}(\boldsymbol{x}_s^{j-1})$. As the STD σ_j when forming the set H_{js} we can consider the maximum distance between the points of the set C_{j-1}: $\sigma_j = \max|\boldsymbol{x}_k^{j-1} - \boldsymbol{x}_l^{j-1}|, (\boldsymbol{x}_k^{j-1}, \boldsymbol{x}_l^{j-1}) \in C_{j-1}$. This makes it possible to ensure the intersection of sets of points formed in multidimensional spheres with centers at points $\boldsymbol{x}_k^{j-1} \in C_{j-1}$, and therefore more fully and uniformly take into account the region C_{j-1}.

C. Adaptive Sampling Algorithm

The main problem of methods of nested subspaces of states is the dependence of the resulting data on the mechanism of formation of intermediate sets. In this case, situations are possible when the subsequent subspace practically does not change the criterion threshold $b_k \approx b_{k-1}$, which leads to the lack of convergence of the computational process for a given number of iterations. In this case, the resulting probability of a rare event becomes arbitrarily small. Hence, the main directions of research in this area are aimed at increasing the robustness of the methods. There are a fairly large number of proposals for the formation of intermediate sets [22-25]. Along with the monocentric methods described above, we proposed and tested the adaptive sampling method, the essence of which is the multiple adaptive correction of the parameters (mean and variance) of the distribution of the intermediate sample. Its steps are as follows:

1. Initialization: $k = 1$; $N_c = p_0 N$; $N_s = 1/p_0$; $\lambda = 0.6$
2. Generation according to the standard normal (Gaussian) distribution of N pseudo-random numbers: $U = \{\boldsymbol{u_1}, \ldots, \boldsymbol{u_N}\}$.
3. Transformation of the set U into a matrix $X = \{\boldsymbol{x_1}, \ldots, \boldsymbol{x_N}\}$ of named random variables (load, generation, state of the system elements), according to their marginal distribution laws $\boldsymbol{x}_i = \varphi_i(\boldsymbol{u}_i)$.
4. Definition of the vector of criterion functions $\boldsymbol{\psi} = \{\psi_i(\boldsymbol{x_i})\}$ and its sorting in ascending order of the function: $\psi_i(\boldsymbol{x_i}) \geq \psi_{i-1}(\boldsymbol{x_{i-1}})$
5. Determination on the set $\boldsymbol{\psi}$ of the percentile $(p_0 \cdot 100)$, the parameter $b_k \geq 0$ corresponding to it, and the set of named significant states of the system $H_{xk} = \{\boldsymbol{x_i}: \psi_i(\boldsymbol{x_i}) < b_k\}$.
6. Generation of a new sample of N random states of the system based on the reference states of the system.
7. Items 4-6 are repeated until $b_k \geq 0$. In this case, the conditional probability $Pr(H_k|H_{k-1}) = p_0$. At the last step m, for $b_m < 0$ the number N_m of elements is determined that satisfy the condition $\psi_{N_m}(\boldsymbol{x}_{N_m}) \leq 0$, $\psi_{N_m+1}(\boldsymbol{x}_{N_m+1}) > 0$. The resulting probability of a rare event is $\Pr(H) = p_0^{m-1} N_m / N$.
8. Determination of other analyzed probabilistic indicators (mean of PD, etc.).

IV. Cross entropy method

The cross-entropy method (CEM) [26-28] is based on replacing the real function $f(\boldsymbol{x})$ of the distribution density of the analyzed multivariate random variable, according to which the MCM is sampled, by some auxiliary PDF $q(\boldsymbol{x})$, which shifts the scope of analysis into the region of interest of a rare event. This approach is widely known in the calculation of integrals of complex functions by statistical methods, where the integrand is multiplied and divided by some PDF, completely defined on the integration interval under consideration:

$$\int_a^b f(x)dx = \int_a^b \frac{f(x)}{q(x)} q(x)dx = \mathbb{E}_q\big(W(x)\big) \cong \frac{1}{N}\sum_{i=1}^{N} W(x_i),$$

where $W(x) = f(x)/q(x)$. In this case, the problem of choosing an auxiliary function arises - it is necessary that the calculation procedure based on it be not only adequate in direction (shift of the analyzed area towards a rare event), but also efficient in terms of speed and convergence. In the presence of CDF, the probability of power shortage (2) can be represented as the mathematical expectation of the weighted indicator function $J(\boldsymbol{x})W(\boldsymbol{x})$, defined in a multidimensional space of random variables with a density function $q(\boldsymbol{x})$:

$$\mathbb{P}_H = \int J(\boldsymbol{x})\frac{f(\boldsymbol{x})}{q(\boldsymbol{x})} q(\boldsymbol{x})d\boldsymbol{x} = \int J(\boldsymbol{x})W(\boldsymbol{x})q(\boldsymbol{x})dx = \mathbb{E}_q[J(\boldsymbol{x})W(\boldsymbol{x})], \tag{3}$$

where $W(\boldsymbol{x}) = f(\boldsymbol{x})/q(\boldsymbol{x})$ – is the weight function determined by the initial $f(\boldsymbol{x})$ and auxiliary $q(\boldsymbol{x})$ distribution densities. When choosing the most efficient function $q^*(\boldsymbol{x})$ in the class $\{q(\boldsymbol{x})\}$, the minimum of the variance $\mathbb{P}_H$ can serve as an optimization criterion:

$$\min_q \mathbb{V}_q\big[J(\boldsymbol{x})W\big(\boldsymbol{x}; q(\boldsymbol{x})\big)\big].$$

Theoretically, the best function leading to zero variance of the desired probability estimate $\mathbb{P}_H$ is the function [28]:

$$q^*(\boldsymbol{x}) = \frac{J(\boldsymbol{x})f(\boldsymbol{x})}{\int J(\boldsymbol{x})f(\boldsymbol{x})d\boldsymbol{x}} = \frac{J(\boldsymbol{x})f(\boldsymbol{x})}{\mathbb{P}_H}. \tag{4}$$

Since the optimal CDF depends on the unknown values $\mathbb{P}_H$ and $J(\boldsymbol{x})$, a direct analytical determination of $q^*(\boldsymbol{x})$ is impossible. A sufficiently good approximation makes it possible to obtain a FEM based on the successive refinement of the parameters $\boldsymbol{v}$ of the multidimensional distribution density $q(\boldsymbol{x}; \boldsymbol{v})$and the procedure for determining the resulting value is represented as a Markov chain with the choice of parameters at each step. To estimate the parameters $\boldsymbol{v}$, this method uses the results of intermediate statistical tests. The parameter vector $\boldsymbol{v}$ is determined by minimizing the cross entropy (KL divergence) [28]. KL-divergence determines the measure of proximity of two arbitrary PDFs: the optimal PDF $q^*(\boldsymbol{x})$ and its current estimate $q(\boldsymbol{x}; \boldsymbol{v})$. In the proposed work, the function $q(\boldsymbol{x}; \boldsymbol{v})$is represented by the density of a multidimensional normal distribution with the mathematical expectation $\boldsymbol{\mu}_q$ and the matrix of correlation moments Σ_q. In this setting, the degree of optimality, in essence, determines the vector of parameters $\boldsymbol{v} = [\boldsymbol{\mu}_q; \Sigma_q]$).

CEM solves the problem of optimization iteratively by determining a series of intermediate distribution densities $\{q(\boldsymbol{x}; \boldsymbol{v}_k),\ k = 1, \dots, NT\}$, which, as shown in Fig. 2, gradually approach the target density $q^*(\boldsymbol{x})$, representing region of existence of a rare event. At step k, the optimal PDF $q^*(\boldsymbol{x})$can be represented by the estimate $q(\boldsymbol{x}; \boldsymbol{v}_{k-1}^*)$ with the optimal parameters $\boldsymbol{v}_{k-1}^*$ obtained at the previous step. In this case, $W(\boldsymbol{x}; \boldsymbol{v}_{k-1}^*) = f(\boldsymbol{x})/q(\boldsymbol{x}; \boldsymbol{v}_{k-1}^*)$. The area H_k of the intermediate set of system states is determined by the threshold b_k:

$$H_k = \{\boldsymbol{x}: \psi_k(\boldsymbol{x}) < b_k\},$$
$$J_k(\boldsymbol{x}) = \begin{cases} 1, & \psi_k(\boldsymbol{x_k}) < b_k; \\ 0, & \psi_k(\boldsymbol{x_k}) \geq b_k. \end{cases} \tag{5}$$

The threshold b_k is calculated as a θ-quantile (for example, a decile obtained during statistical tests and sorted from the smallest to the largest values of the threshold function $\psi_i(\boldsymbol{x_i})$. In this case, the simulation is performed according to the distribution density $q(\boldsymbol{x}; \boldsymbol{v}_{k-1})$ with parameters

$\boldsymbol{v}_{k-1}$.

The vector $\boldsymbol{v}^*$ obtained as a result of solving the optimization problem at step $k-1$ is considered as a new value of the vector of parameters of the optimal PDF $q^*(\boldsymbol{x})$, $\boldsymbol{v}_k = \boldsymbol{v}^*$. Starting from the initial vector of parameters $\boldsymbol{v}_0$ that is assumed to be equal to the initial parameters of the probability distributions of the analyzed random variables, each subsequent vector $\boldsymbol{v}_k$ is determined by the solution of the optimization problem, approaching the optimal distribution density $q^*(\boldsymbol{x}) = \lim_{k\to\infty}(q(\boldsymbol{x};\boldsymbol{v}_k))$, which, in turn, is the best estimate of the auxiliary PDF optimal in the CEM. The procedure is repeated until b_k becomes negative, or at least $\theta \in [0.01, 0.1]$ trials are located in the desired region of rare events [28]. If the number of steps to reach the termination criterion of the iterative process is m, then the resulting probability of a rare event is:

$$\hat{\mathbb{P}}_F = \frac{1}{N}\sum_{i=1}^{N} J(\boldsymbol{x}_i)W(\boldsymbol{x}_i;\boldsymbol{v}_{m-1}). \tag{6}$$

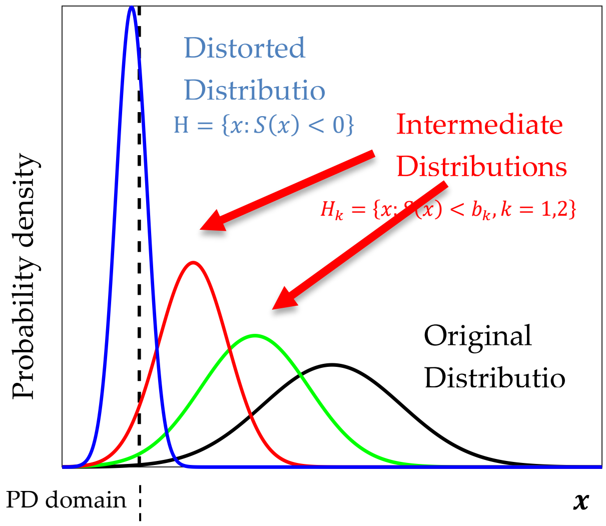

Figure 2: *Derivation of distorted probability distribution using CEM*

The classical CEM presented above requires an optimization procedure to be performed when determining the parameters $\boldsymbol{v}_k$ of the current PDF $q(\boldsymbol{x}, \boldsymbol{v}_k)$. In this case, $\boldsymbol{v}_k$ includes the mean $\boldsymbol{\mu}_k$ and the matrix of correlation moments Σ_k of those realizations x that belong to the area H_k, $\boldsymbol{x} \in H_k$. Expression (6) can be considered as the average value of the values $J_F(\boldsymbol{x}_i)$ with weights $W(\boldsymbol{x}_i)$. Since it refers to a probability, each component of the sum can be interpreted as the probability that the realization $\boldsymbol{x}_i$ belongs to the current region H_k of the rare event. Since the area $H_k$is defined by the indicator function $J_k(\boldsymbol{x}_i)$, then the mean of the available power of nodes in the area H_k is as follows:

$$\boldsymbol{\mu}_r^{(k)} = \left(\sum_{x_i \in H_k} \boldsymbol{x}_i W_i\right) / \left(\sum_{x_i \in H_k} W_i\right).$$

Matrix of correlation moments can be expressed as follows:

$$\Sigma_r^{(k)} = \left(\sum_{x_i \in H_k} W(\boldsymbol{x}_i)(\boldsymbol{x}_i - \boldsymbol{\mu}_r^{(k)})(\boldsymbol{x}_i - \boldsymbol{\mu}_r^{(k)})^T\right) / \left(\sum_{x_i \in H_k} W(\boldsymbol{x}_i)\right).$$

These parameters form the vector $\boldsymbol{v}_k$. With this approach, an optimization procedure is not required, which significantly reduces the duration of calculations without a significant decrease in the accuracy of the results.

V. Computational results

To compare the described procedures, calculations of the balance reliability indicators are performed for a five-node electrical circuit shown in Fig. 3, where in addition to the topology, load and generation expectations are presented. Standard deviations are taken equal to 10% of expectations. TLs, numbered in the order {1-5; 1-4; 4-5; 2-4; 2-3; 3-4}. TL have resistances respectively R = {10; 5; 5; 3; 1; 2}; X = {100; 50; 50; 50; 33; 10; 10}. The limiting capacity of all connections was taken equal to 500 MW.

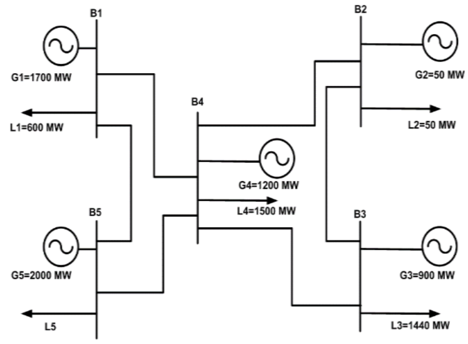

Figure 3: *Test circuit*

The calculation results are presented in Table I, where the methods are indicated: MCM – classical Monte Carlo method; Monocenter – subspace method with one point of formation of an intermediate subspace; Polycenter – the set H_{k-1}; is taken as reference points for the formation of the intermediate subspace H_k; SubSet– method of subspaces with changing parameters of probability distributions when forming an intermediate subspace; CEM– simplified cross-entropy method.

Table 1: *Computational results*

Methods	Pr, 10^{-5}	Pr, Cv	Pr_Eps, %	mD, 10^{-4}	mD, Cv	mD_Eps, %	t, sec
Convolution	2.23	0	0	1.21	0	0	0
MCM	2.23	0.07	0.1	1.21	0.10	0.1	19
Monocenter	2.24	0.6	0.5	1.48	0.90	22.1	0.44
Polycenter	2.29	0.65	2.9	1.52	0.92	25.7	0.19
SubSet	2.2	0.58	-1.4	1.41	0.92	16.7	3.21
CEM	2.3	0.54	3.3	1.24	0.03	2.5	0.12

The second column presents the calculated probability of the total power deficit of the EPS. It should be noted that all presented methods show an accuracy of a rare event acceptable for practical calculations - a maximum deviation of 3.3% (column Pr_Eps, %, CE method) with an exact probability value Pr = 2.23×10–5 can be considered insignificant for low probabilities. For comparison, it can be mentioned that with such probabilities, the widespread replacement of the binomial distribution with the Poisson distribution has a much larger error. The coefficient of variation presented in the Pr_Cv column shows that the spread of the resulting probabilities is relatively small for all methods.

The next 3 columns refer to the mean of PD. Here the spread (coefficient of variation (column mD, Cv)) of the resulting values is much greater. It should be noted that the relative error in calculating the mean of the PD exceeds 25%. Increasing accuracy is possible by increasing the volume of the intermediate sample. However, this leads to an increase in the duration of calculations (column t), which in the presented calculation procedures depends mainly on time-intensive transformations of probability distributions (uniform- Gaussian- individual (marginal)). If we assume that all random variables are described by the same normal distribution (with different parameters), then this allows us to reduce the duration of calculations several times.

The results obtained allow us to recommend cross-entropy methods for practical use that provide the smallest scatter of the resulting indicators.

VI. Conclusion

The described methods for identifying rare events in the electric power industry refer to those events for which it is possible to determine a criterion function that changes its value depending on the distance from the desired events. Such functions (and events) in the electric power industry include power shortages, positive when there is a shortage and negative when there is a reserve of generating capacity. The main technology for identifying rare events is the use of Markov chains, where each subsequent event is determined on a set of events identified at the previous stage according to some criterion. Of the existing approaches to identifying rare events, two can be identified that are most suitable for technical systems: those based on the use of nested subspace technology and the transformation of distribution functions of random variables (including entropy methods). It can be noted that all the procedures considered make it possible to identify rare events with an accuracy acceptable for practical use. According to the robustness criterion, preference can be given to the adaptive sampling algorithm from the class of nested subspaces and the modified cross-entropy method from the class of distribution function transformations. The accuracy of the calculations largely depends on the settings of the methods, including the size of the test sample at the intermediate stages of forming significant events. In this case, the duration of calculations is determined not only by the sample size, but also by the need for probabilistic transformations of distribution functions.

Abstract

Natural hazards, such as avalanches, are common in the mountainous regions of Georgia. They pose a great danger to the population, cause destruction, paralyze sections of roads, and often cause casualties.
Racha-Lechkhumi Kvemo Svaneti region of Georgia belongs to the high mountain region (400-4000 m. above sea level). The region is characterized by steep slopes and abundant snowfall. Therefore, avalanches are not a rare event in the region. Snow avalanches especially damage the road infrastructure that connects the municipalities of the region. In winter, the blocking of road sections by avalanches from the slopes threatens the surrounding populated areas, causes ecological problems and human casualties are frequent.
Meteorological elements: air temperature, snow cover, precipitation are studied on the research sections of the highways of the region. The data is processed according to the data of two weather stations in the region (Oni, Mamison Pass) and covers the last 60 years. Based on the results of the research. A geo-informational map of avalanche hazards of road sections of the Racha-Lechkhumi Kvemo Svaneti region has been compiled.
The conducted research will significantly contribute to the implementation of correct and effective anti-avalanche measures, reducing the economic losses of the country.

Keywords: natural disaster, avalanche, climate, road infrastructure, geoinformation map

I. Introduction

Snow avalanches are one of the most important natural disasters. The purpose of the study is to investigate the avalanche danger of the Racha-Lechkhumi and Kvemo Svaneti highways in the mountainous region of Georgia, the smooth operation of which is important for the sustainable development of the country.

Based on long-term (>60 years) data from meteorological stations and checkpoints in Georgia, regions with little snow, medium snow, no snow, and especially no snow are distinguished according to the amount of snow. The maximum height of the snow cover in the area with little snow varies from 30-50 cm to 140-160 cm in the area with average snow. The maximum height of the snow cover increases with the increase in the absolute altitude of the place and is from 60-100 cm to 450-500 cm in the area without snow the maximum height increases from 100–120 cm to 550–600 cm, and the maximum height of the snow cover changes from 100–120 cm to 700–750 cm in a particularly snowless area [1].

Therefore, it is logical that 56% of the territory of Georgia is covered with avalanche-prone slopes, catastrophic avalanches spread over 36% of the territory, avalanches occur annually on 20% of the territory, and sporadic, rare avalanches occur on 36% of the territory, which are possible to repeat once a year or several decades [2].

According to the data of the National Environmental Agency, there are more than 5,000 identified avalanche traps in Georgia [3].

Avalanche risk in mountainous regions of Georgia depends on topography (orography, hypsometry, and slope inclination), climate (air temperature, atmospheric precipitation, and snow cover), and vegetation cover. Evaluation of the above-mentioned elements allows for the determination of the origin, mode, and distribution characteristics of avalanches [4-6}.

Four main quantitative characteristics determine the degree of avalanche danger in the territory of Georgia:

- avalanche activity of the area (active area in terms of avalanche formation);
- Avalanche distribution frequency (number of avalanches per area unit);
- frequency of arrival of avalanches (the number of arrivals of avalanches from the avalanche reservoir in one winter);
- Duration of the avalanche period (number of avalanche days in one winter) [7,8]

On the territory of Georgia, especially strong, strong, medium, weak, and non-avalanche-prone areas are distinguished (Fig. 1) [9]. The percentage of their sea hazards is presented in Fig.2.

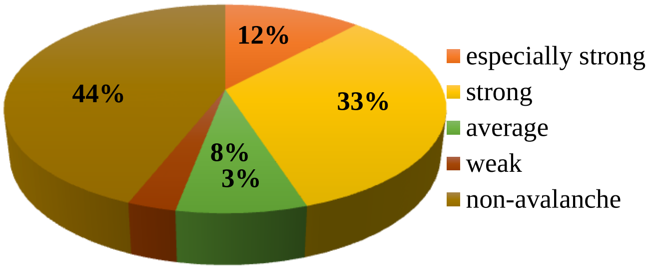

Figure 2: *The percentage of the degree of avalanche danger in Georgia.*

II. Methods

Area under study

The object of our research is one of the regions of Georgia, Racha-Lechkhumi and Kvemo Svaneti (Fig. 3). It is located on the southern slopes of the Central Caucasus and belongs to the high mountain zone (400–4000 m) [10].

Figure 3: *Racha-Lechkhumi and Kvemo Svaneti region. Source: http://rachalechkhumi.blogspot.com/2014/ [11]*

The region is rich in mountain resorts: Shovi, Usira, Lashichala, Veshwake, Muashi, Sortuan, Bugeuli, Khidikar. There are many types of healing mineral or sulphurous waters in the region. From the point of view of tourism, it is distinguished by the abundance of attractive objects.

On the territory of the region, we can find the oldest churches: Nikortsminda, Barakoni, Khonchiori, Mootdzali, Patara Oni, Ghe, Kviriketsminda, Laila, Chazhashi complex, Minda-tsikhe, Kvaratsikhe, the oldest complexes of castles - "Dakhdi", "Dahkari", "Arr Latsa", Oni Synagogue, Shaor and Lajan reservoirs, etc. [12]. All of the above emphasizes the need for proper functioning of the road infrastructure in the region.

Racha has humid weather up to 2000 m above sea level, winter is cold and long, summer is short and warm, absolute minimum temperature is -27 °, and the maximum is 36°. Precipitation ranges from 1000–1500 mm to 1600–1800 mm.

As for the maximum height of the snow cover, in general, it ranges from 127 cm to 535 cm in

Racha-Lechkhumi and Kvemo Svaneti (Table 1).

Table. 1: *The maximum height of the snow cover in Racha-Lechkhumi and Kvemo Svaneti*

Weather station	Altitude of weather station	Years of observation	Maximum height, cm	Recurrence of snow cover height of more than 50 cm, (cm/year)				
				>50-100	101-200	201-300	301-400	>400
Ambrolauri	544	1932-2021	165	25	6	-	-	-
Oni	788	1932-1998	127	21	3	-	-	-
Shaori	1145	1948-1988	255	21	19	4	-	-
Uravi	1150	1939-1990	230	19	6	1	-	-
Shovi	1507	1935-2021	365	24	30	4	1	-
Mamison Pass	2854	1935-1992	535	31	11	6	-	1

The Table 1., presents the height of meteorological stations and checkpoints, the years of observations, the maximum snow height, and the recurrence of the snow cover height of more than 50 cm by year [13].

As it can be seen from the presented material, in the territory of Racha-Lechkhumi and Kvemo Svaneti regions, according to the indicators of avalanche danger (Fig. 1.), especially strong, strong, and average avalanche-risk areas are separated.

The detection of avalanche-prone sections on the highways of the Racha-Lechkhumi and Kvemo Svaneti regions was based on the existing materials of many years of field studies, the databases of the National Environment Agency, information and publications published in literary sources, and the fundamental studies of the Shota Rustaveli National Science Foundation (grant FR 21-1677). Materials and data from field expeditions carried out in 2022 During the field work, the avalanche hazard of each research road section of Racha-Lechkhumi and Kvemo Svaneti region was studied. In particular, a drone (dji mavic 3) was used to describe the locations of avalanche arrivals on road sections, the location of avalanche collectors, and collect photo and video material in areas of avalanche danger where it is impossible to reach on foot.

III. Results

The morphometric (beginning and end height, length, focal area, surface slope) and dynamic characteristics of the avalanche (maximum speed and impact force, cone volume, and maximum height of the moving avalanche) of the area avalanche on the highways of Racha-Lechkhumi and Kvemo Svaneti region are presented in Table 2.

Table 2: *Morphometric and dynamic characteristics of dangerous avalanches of Racha-Lechkhumi and Kvemo Svaneti highways*

In the table of morphometric and dynamic characteristics of avalanches, columns 2–9 provide data on the absolute and relative height of the avalanche and its separate sections, horizontal and actual length, surface slope, and area of the avalanche center. Columns 10–15 present numerical data on the values of avalanche speed and impact force, avalanche cone volume, moving avalanche snow height, avalanche length, and the absolute height of the avalanche stop on a separate section of the avalanche collector. The last column of each avalanche description indicates the place where the avalanche will stop.

e.g. It will pass by the building, cross the river, cross the road, and stop on the opposite slope. In addition to these numerical data, the location of each avalanche is given (river valley, height of the mountain, or peak where the avalanche begins). The settlement and the main object of our research are indicated a road where an avalanche can cause damage. A minus sign in front of the number in the third column indicates that the avalanche crossed the road, ravine, or river and stopped on the opposite slope.

By combining the existing basic data and the data of our expeditionary works, we were able to create a modern, large-scale geo-informational maps of the avalanche danger of highways in the Racha-Lechkhumi and Kvemo Svaneti regions (Fig. 4; Fig. 5).

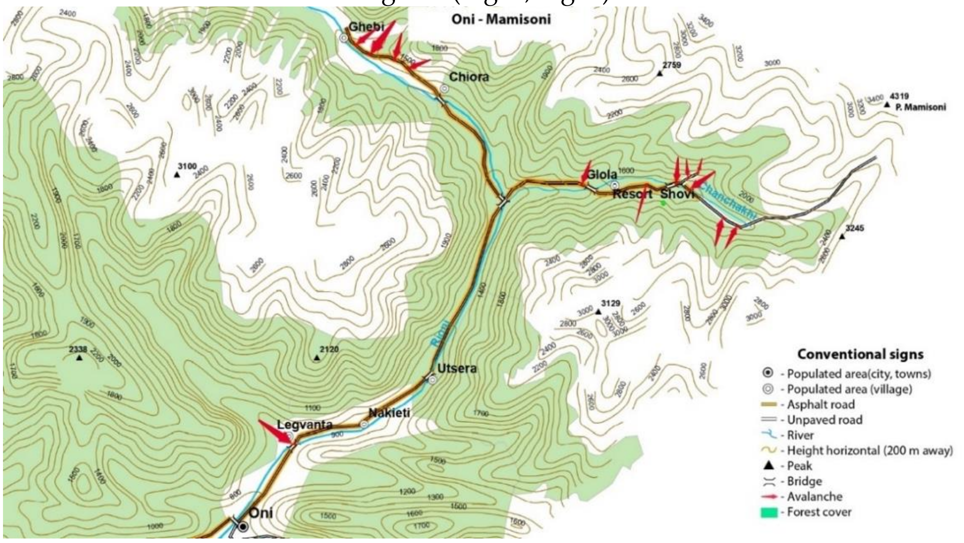

Figure 4: *Avalanche hazard map of Oni-Mamison section of the highway of Racha-Lechkhumi and Kvemo Svaneti region*

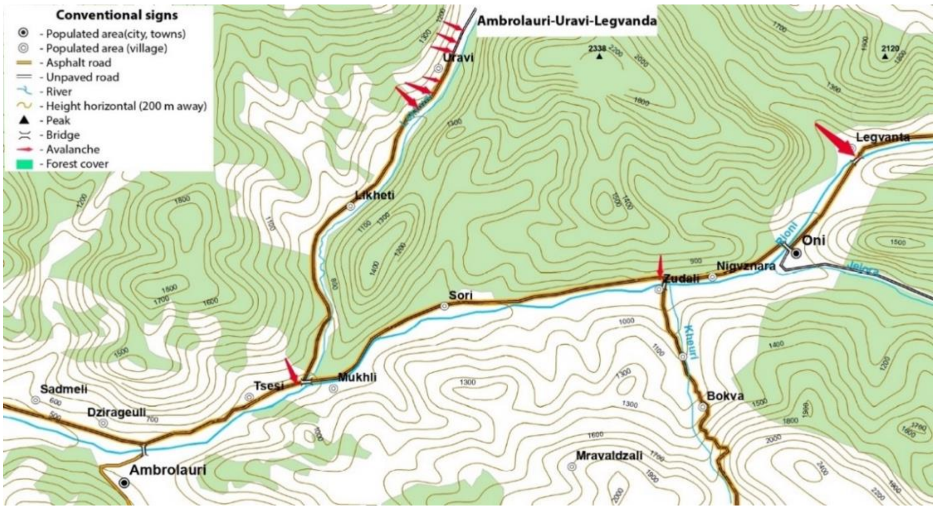

Figure 5: *Avalanche hazard map of Ambrolauri-Uravi-Legvanda section of the highway of Racha-Lechkhumi and Kvemo Svaneti region.*

IV. Discussion

Out of 76 avalanche collection points in the territory of Racha-Lechkhumi and Kvemo Svaneti region [14], 57 were identified, where in the event of an avalanche, a specific section of the highway is included in the area of avalanche arrival, that can cause damage to road infrastructure and, in some cases, human casualties.

The conducted research revealed that there are avalanche-prone areas on the highways of all four municipalities in Racha-Lechkhumi and Kvemo Svaneti region. Among them, Lentekhi municipality (48 sections), Oni municipality (4 sections), Ambrolauri municipality (3 sections), and Tsageri municipality (2 sections) are distinguished by the intensity of avalanche-prone areas. The slopes of 11 rivers and 31 rural areas of the region fall within the area of the highway's avalanche-prone area (Table 3.).

Table. 3: *Villages and Rivers with avalanche danger of highways section according to municipalities*

Villages with avalanche danger highways section according to municipalities				Rivers with avalanche slopes
Oni	Ambrolauri	Tsageri	Lentekhi	11
4	1	3	24	

V. Conclusions

Based on received data, processing

- Avalanche-risk highways of Racha-Lechkhumi and Kvemo Svaneti region were studied, and their climatic characterization will be done;
- Geo-informational maps were created - a schematic maps of each avalanche-prone road in the region;
- The morphometric and dynamic characteristics of each avalanche were calculated.
- The place of landing and stopping of the avalanche was indicated;
- The frequency of avalanches was determined according to the amount of snow.
- The obtained results will be the basis for the preparation and implementation of anti-avalanche works on the highways of the mountainous regions of Georgia.

CURRENT CONCEPT OF RISK: THE HIGHER THE PROBABILITY OF AN EVENT, THE LOWER THE RISK

Alexander Fedorets

•

alfed1961@gmail.com

Abstract

With the adoption of a new concept of risk in the economy (ISO 31000:2009), the main task of risk assessment is to justify the adoption of management decisions under conditions of uncertainty. Within the framework of the new concept, a new fundamental definition of risk (risk - the effect of uncertainty on objectives) was established. The most important practical consequence of the new concept of risk was introduction of concept "likelihood" instead of "probability". Another paradoxical conclusion follows from the current definition of risk, which is important for understanding the essence of risk and improving risk assessment methodologies in current conditions is: the higher the probability of occurrence of the assessed event, the lower the "actual risk" associated with this event.

Keywords: risk, probability, likelihood, uncertainty, OHSI method

I. Causes and consequences of the risk management revolution

In 2009 (ISO 31000 standard) the revolution in understanding of risk and tasks of risk management, which actually began at the end of the XX century, was completed. However, this event, its causes and consequences have not yet been sufficiently noticed and studied by both the scientific community and practitioners.

To assess the value of risk, the past conception used the following definition: risk is a combination of the severity of possible harm and the probability of occurrence of this harm. This is a particular variant of the modern fundamental definition, which leaves open the question of what we mean by "harm" (whose harm, what is harmed) and what "probability" we mean (objective or subjective).

Let us call this approach technocratic, because it is focused on risk assessment in the area of presumably known initial data, is based on precise mathematical methods, and its central element is the very process of obtaining values of risk elements (probability and harm) without taking into account the possibility of its further use of results in the interests of risk management.

Since in the previous (before 2009) assessment of risk value was associated with the term "probability" (probabilistic risk assessment, PRA), the methods of classical probability theory, statistical methods were used for its assessment.

It is not difficult to see that if we use these methods to estimate probability, then:

- we assume a high degree of confidence in the initial data, which are based either on reliable statistics of the flow of homogeneous random events, or knowledge of the actual state of all elements of the system at any point in time;
- as a result of such an assessment, we do not receive a risk value for decision-making purposes, but a reasonable forecast of the state of the system for a given period, assuming that the input data included in the risk assessment remain unchanged;
- management decision-making in such a model is based not on uncertainty and risk assessment, but on predetermination and confidence in the preservation of the established trend.

At the same time, obviously, we cannot use the classical approach to assessing probability when assessing the risk of rare or unique events, where we must use the term "likelihood" and apply fundamentally different methods of assessing likelihood rather than probability.

The modern definition of risk (risk - the effects of uncertainty on objectives) puts in the center of the risk management problem namely the uncertainty of the future and implicitly introduces the main actor of risk management - the owner of risk (decision maker, LPR), who is both the owner of the goal and responsible for the failure to achieve the goal as a result of risk realization.

Risk assessment within the framework of the modern concept is based on the following assumptions:

- the situation in economy, politics, technology, social relations is changing so fast these days that any past statistics loses its meaning (there are no statistics);
- events of interest to the risk manager (decision maker) are so rare and differing in essential features (not homogeneous) that it is impossible to form a representative sample of them (there are no frequency);
- development of technologies (innovations) requires risk assessment in the absence of information about similar activities and similar events (there were no similar events at all).
- the purpose of risk assessment is to assess the magnitude of the impact of an unfavorable event on the purpose of the activity (comparison of the purpose of the activity, probable damage and costs for the implementation of preventive measures).

Despite the fact that the objective needs to change the concept of risk arose at the end of the XX century, in economics the new concept of risk was formalized only in 2009 with the release of the international standard ISO 31000).

Nevertheless, until now among modern scientists and practitioners dealing with the problems of risk assessment, the followers of the previous concept of risk, based on objective probability, certainly prevail [1, 2, 3]. It is interesting to note that the PRA approach is also used to assess the risks of such rare events as earthquakes [4] or events that have not yet occurred [5].

The promoters of the subjective-probabilistic approach, to whom the author includes himself, are still underrepresented both in scientific publications and in practical developments.

A detailed analysis of these two views is given, for example, in [6].

II. The higher the probability of an unfavorable event occurring, the lower the risk. Paradox or obviousness?

The term "probability" is usually understood as either a frequency probability, somehow related to statistics (representative sample) of past similar cases, or to a homogeneous flow of events, or to the availability of reliable objective information (facts) about the possible occurrence of this or that event. From which we can conclude that a rating of "probably" means a high degree of confidence that the event is " very likely" to occur in the foreseeable period of time. A high degree of certainty that an event is "very likely" to occur means a low level of uncertainty about the decision to respond to that event.

Estimates of the probability of low-probability events can be obtained with a high degree of confidence on the basis of large-scale sampling (thousands of homogeneous events) or accurate knowledge of the actual characteristics of a system or process (based on objective research or monitoring). This case is characteristic of statistical methods used, for example, in quality management systems (QMS) in mass homogeneous production.

However, in risk management such a situation seems to be fundamentally impossible. For rare or unique events occurring in the sphere of economy, politics, global cataclysms (earthquakes, tsunamis), the estimation of probability (more precisely - likelihood) of occurrence of such events can be obtained only with a very low degree of reliability. This excludes the possibility of their use for decision-making purposes.

On the contrary, a low level of uncertainty means low effects of uncertainty on objectives and therefore low risk in decision making, regardless of the magnitude of the probability! Therefore, risk as effects of uncertainty on objectives (i.e., within the 2009 concept) decreases simultaneously with the reduction of uncertainty both in terms of estimating the magnitude of harm and in terms of estimating the probability of an event occurring.

This article deals with "risk" within the framework of the modern concept of 2009 (ISO 31000), which in the limit allows for the complete absence of information about past events. The degree of probability of occurrence in the future of an extremely rare in the past or unique event is negligible, but the occurrence of the event is not excluded, which determines the high level of uncertainty and its effect on the decision on the need to take measures to respond to the risk. Therefore, instead of the term "probability" in the framework of the modern concept of risk, the term "likelihood" is used, which initially implies a low degree of confidence both in the initial data and in the results of probability and risk assessment.

As is known, when designing the protection of the Fukushima NPP, it was assumed, based on previous observations, that earthquakes with a magnitude of more than 8.5 were "practically" impossible. Nevertheless, the main shock occurred with a magnitude of 9.1, which caused a tsunami wave whose height in the area of the plant exceeded the calculated height by almost 10 meters. It should be noted that according to some studies, earthquakes with a magnitude of more than 9 in this area were accepted as "extremely unlikely".

This is the seeming paradox: at high values of event probability, risk assessment for decision-making purposes does not require special knowledge or techniques, since taking measures to reduce risk is obviously necessary if the damage is assessed as unacceptable. This conclusion is valid in the area of evaluating the possibility of the event occurrence, where we can speak exactly about "the probability", i.e. the event is more expected than impossible.

At the same time, the maximum risks of decision-making are associated precisely with rare or unique events, the probability of occurrence of which is negligible, but not excluded (likelihood), and damages (harm) are assessed as critical or catastrophic. These events are characterized by low probabilities and extremely high degree of uncertainty.

Therefore, the statement "the higher the probability, the lower the risk" is true only within the framework of the modern concept of risk (2009), where the definition "risk - the effects of uncertainty on objectives" is used, and the concept of likelihood is used instead of probability.

Thus, the use of "likelihood" instead of "probability" in the modern concept of risk is not just a formal replacement of the term, but a fundamentally important distinction, reflecting a change in the focus of attention in risk assessment from statistically expected events, the possible effects of which on objectives have already been taken into account, to low-probability events that have critical effects of uncertainty on objectives, and their consideration in management is characterized by high cost and uncertainty.

III. The essence of uncertainty in risk management

The key concept of the modern concept of risk is uncertainty. Physics and computer science use the concept of uncertainty, similar to the concept of entropy, which reflects the measure of uncertainty in the state of any system. To estimate the amount of uncertainty (information entropy) Shannon's formula is used [7]

$$H_e(x) = -\sum_{i=1}^{n} P_i \; log_2 \, P_i. \tag{1}$$

It follows from the Shannon formula that the uncertainty value H_e is related to the probability of an event nonlinearly, $H_e \to 0$ if $P \to 1$ and $P \to 0$ and has a maximum near the point $P \approx 0.37$ (Fig.1).

Although the uncertainties of the credible (P=1) and the impossible (P=0) events are equal in the limit, however, it is just as obvious that the information entropy function behaves differently in areas close to 0 and close to 1.

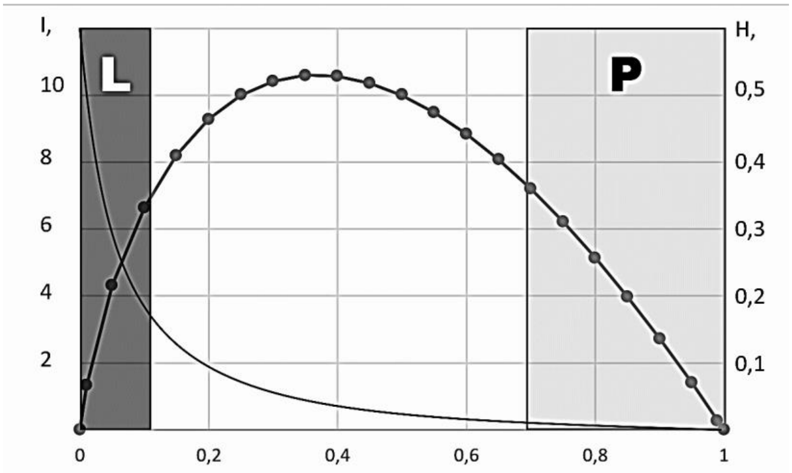

Figure 1: *Probability, likelihood and uncertainty*

The uncertainty of occurrence of extremely unlikely events (L, likelihood, q) is indeed substantially larger than that of their corresponding extremely likely (P, probability, P=1-q) events.

In general, formula (1) describes the uncertainty of the current state of the system, which is characterized by N possible states. That is, the entropy measure is the difference between the information contained in the new message and the part of information that is precisely known (or well predictable) in the message.

However, in the field of risk management, due to the lack (absence) of precisely known information, the general assessment of uncertainty (uncertainty) of the state of the system as a whole is not of practical importance. The decisive value is the assessment of certainty (certainty) of finding the system in a certain specific state from the set N or the possibility of transition of the system to such a state. Consequently, in the field of risk management it is necessary to consider uncertainty not in the form of information entropy, but in the form of self-information (2), which is a measure of uncertainty (unexpectedness) of occurrence of a certain event or being of the system in a certain state.

$$H_s\ (x) = -log_2\, P_x. \qquad (2)$$

That is why the ISO 31000 standard introduces the concept of uncertainty not in the form of information entropy, but in the form of self-information, i.e. complete or partial absence of information necessary to understand an unfavorable event, its consequences and their probabilities. In purposeful activity, the probability of a favorable outcome is much (by orders of magnitude) higher than a negative one, and its uncertainty is significantly lower. Therefore, in risk management, the probability of a negative outcome is usually considered, because a favorable outcome is expected (planned and ensured).

Passing in the uncertainty assessment from the information entropy formula to self-information, we will see even more significant difference in the values of uncertainties in the areas P and L (see the table below).

For example, if the values of uncertainty H at probability values $P_P = 10^{-1}$ and $P_L = 10^{-3}$ differ in times, then the values of uncertainties at the magnitude of the lack of self-information differ by four orders of magnitude.

Thus, a high probability of being a system in a critical (dangerous) state contains a low uncertainty and, accordingly, a low level of risk in making a management decision to prevent the

RT&A, Special Issue № 6 (81), Part-1,
Volume 19, December 2024

dangerous situation: "unambiguously - to act!". Conversely, a low probability of the system being in a dangerous state contains a high level of uncertainty: whether to act (to bear, possibly, excessive costs) to prevent the development of the situation or to wait ("maybe this time it will not happen").

Table: *Significant difference in the values of uncertainties in the areas P and L*

Likelihood (L), q	Probability (P), P=1-q	H_L/H_P	I_L=-log$_2$ L, bit	I_P=-log$_2$ P, bit	I_L/ I_P
0,001	0,999	6,91	9,97	0,001	9970,0
0,01	0,99	4,63	6,64	0,014	474,3
0,05	0,95	3,07	4,32	0,074	58,4
0,1	0,9	2,43	3,32	0,152	21,8

In the framework of the ISO 31000 concept, this leads us to a seemingly paradoxical conclusion: **the higher the probability of a hazardous event (in the P zone), the lower the associated uncertainty in decision making, i.e. the lower the risk of the risk owner.**

At the same time, in the L (likelihood) zone for rare and unique events this rule does not work anymore, because the use of the term “probability” is excluded. And for events with expected catastrophic consequences, not only the assessment of the probability of occurrence of the event on the basis of the classical probability or "frequency", but also the assessment of risk on the basis of the formula "risk - the product of the probability of occurrence of the event by the amount of harm" loses its meaning.

V. The problem of estimating the probability and risk of rare events

As noted earlier, in the presence of a steady stream of events in the past, risk assessment is effectively a prolongation of past losses on the basis of deriving probability from the past frequency of events for future periods (Fig. 2). Generally speaking, this goes beyond the scope of risk management tasks for several reasons discussed in section 1.

When assessing risks caused by rare or unique events, the main task is to estimate the likelihood of their occurrence in the future in the absence of information about their frequency or, in general, about their occurrence in the past, that is, in the absence of any information about the value of probability. This leads to the task of determining the likelihood of occurrence of some event in the future on the basis of information about the current state of the analyzed system.

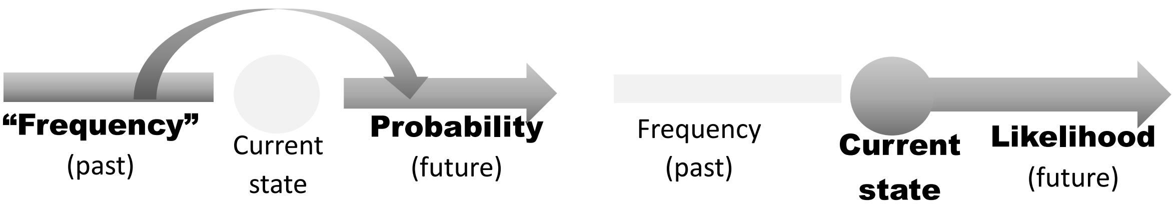

Figure 2: *The evolution of the concept of risk from statistical (on the left) to the concept based on uncertainty (on the right)*

On risk assessment in the L (likelihood) area, we usually do not have sufficient information about the probability of occurrence of events that are known to be rare, unique or assumed to be almost impossible.

In the traditional approach as a value of risk it is accepted to consider a combination of probability of occurrence of a dangerous event and severity of its consequences. In practice, as a combination is considered the product of

$$R = P \cdot W. \quad (3)$$

In the case of critical risks, this approach is not suitable, because the assessment of the probability of occurrence of an extremely unlikely hazardous event has no factual basis, and either does not give an idea of the actual value of the risk, or serves as a source of unfair manipulation. For example, if the estimated amount of harm is billions of dollars, then by simply manipulating the probability value (e.g., to 10^{-6}) the level of risk can be reduced to negligible (thousands of dollars).

In fact, estimates of extremely small probabilities (less than 10-3) are based, usually, on assumptions rather than on facts. Therefore, it is the economic (subjectivist) approach to probability estimation, outlined, for example, as early as in *de Finetti* [8] and developed in [9], that works in this range of probabilities.

De Finetti proposed to estimate the probability of occurrence of the event of interest related to economic consequences on the basis of game theory, weighing the possible benefits and losses from taking a particular decision regarding risk:

the probability of an event is the price *at which the person assigning the probability is neutral between buying and selling a ticket that is worth one unit of payment if the event occurs, and worthless if not.*

In relations to risk assessment, this statement should be understood in such a way that in the case of critical risks, it is advisable to consider a combination of the magnitude of the expected damage, the level of likelihood of causing such harm and the amount of costs for preventing the expected harm

$$(1-q) \cdot C \leftrightarrow q \cdot W,$$

from where it follows

$$q = \frac{C}{C+W} \approx \frac{C}{W} \ ,$$

where W is possible harm (cost); C is the allowable costs of avoiding harm ($C<<W$); q is the subjectively estimated probability of harm ($q<<1$).

That is, based on the de Finetti approach, the likelihood of a dangerous event in risk management is subjectively estimated as the ratio of the allowable costs of preventing harm to the magnitude of this harm. In the given example, it was assumed that protective measures are absolutely effective (E=1) and completely prevent (exclude) a dangerous event and the associated damage W. In fact, any preventive protective measures involve costs (this is, in fact, the essence of the risk problem), but have limited effectiveness E<1. In this case, the total losses W_Σ (the sum of the probable damage W and the cost of preventing it C) will be

$$W_\Sigma = q[EC+(1-E)(C+W)]+(1-q)C \approx C+qW(1-E).$$

If we exclude from consideration the subjective component of q (will happen or will not happen) and assume that the identified possibility of harm as a result of a possible adverse event is still realized (in an arbitrary period of time), then the formula of total losses (residual risk)

$$R_r \approx C+W_\Sigma(1-E),$$

and taking into account the assumptions C<<W, E→1

$$R_r \approx W(1-E),$$

where the expression in parentheses (1-E) represents the total estimated probability of an adverse event, provided protective measures are taken with the overall effectiveness of E.

Based on this approach, the author has developed a risk assessment method, which is called the OHSI Method (OHSI, Occupational Health & Safety Institute) [10], which is implemented in the Russian national standard GOST R 12.0.011-2017. This method was developed for the field of occupational safety, characterized precisely by rare heterogeneous events (frequency 10^{-2} ... 10^{-3} per year per 1000 employees) with significant damage (injuries and deaths of workers at work).

The method is based not on an analysis of the frequency of past allegedly similar events, which do not happen in the field of occupational safety, but on the use of objective information about the availability, protective properties (effectiveness) and the current state of protective measures. In the OHSI Method, the probability (likelihood) of the occurrence of an adverse event is assessed through the effectiveness of protective measures (barriers) that prevent the realization of the danger

$$P=1-E_{\Sigma},$$

where E_{Σ} is the total effectiveness of protective measures, defined in such a way that in the absence of protective measures the probability of occurrence of the event is equal to 1 (credible event), and when the source of danger is eliminated P=0 (impossible event). An example of calculation of E_{Σ} for several protective measures is also given in [10].

For practical application of the OHSI Method, a procedure (technology) has been developed, including two special ranking techniques for establishing the severity of consequences from identified hazards and establishing the effectiveness of protective measures. The registers formed in this way are the measuring tools of the OHSI Method. With the volume of registers more than 20 items, such registers provide quantitative nature of risk assessment and a high degree of objectivity of the risk assessment procedure, which is extremely necessary for the implementation of an effective risk management system of the organization.

The procedure based on the OHSI Method is automated and has been successfully applied in practice in the assessment of occupational injury risks, including as a methodological basis for OH&S management systems (OHSMS).

The disadvantage of the OHSI Method is only apparent when it is applied to critical events: extremely unlikely events (accidents) with catastrophic consequences. To significantly reduce the risk in these cases requires protective measures with a performance of 0.99...0.999, which cannot be confirmed on the basis of the ranking methodology. In this situation, the standard methodology for establishing the effectiveness of protective measures is not sufficiently convincing and requires uncertainty reduction.

As possible solutions to this problem, currently considered are:

- instrumental confirmation (monitoring) of preservation of design structural parameters of the object that affect safety (strength of the structure, condition of the foundation and soil);
- supplementing design structural solutions with special structural measures aimed at increasing the strength and stability of the structure under changed conditions;
- monitoring of availability, application and preservation of design parameters of special protective measures;
- application of statistical methods from the QMS field to identify trends in the change of protective properties (effectiveness of protective measures), etc.

Abstract

Shamakhi-Gobustan oil-gas-bearing region is one of the most promising regions of Azerbaijan due to the hydrocarbon potential of Meso-Cenozoic deposits. Mesozoic, Paleogene-Miocene and Pliocene deposits are widespread in the area.
From north to south, the region divided into tectonic zones such as Northern Gobustan, Central Gobustan, Shamakhi, South-western Gobustan, South-eastern Gobustan and Alat.
In each tectonic element, regional anticlinal zones are separated, which are composed of stratigraphic sedimentary layers of a large range on the earth's surface.
Numerous core samples taken from the Meso-Cenozoic deposits in Shamakhi-Gobustan oil-gas-bearing region were analyzed and their reservoir properties were studied. The reservoir properties of the rocks were analyzed for separate zones and different stratigraphic units.
Carbonate content in the northern zone is relatively high, and the carbonation of the Cretaceous deposits varies in a wide range, from 24% to 93.4%. The average porosity of the rocks was more than 14%. However, these sediments are characterized by good reservoir properties, despite the low porosity in some areas. The highest porosity is typical for the Gizmeydan, Angikharan and Chikilchay areas. However, the areas of the northern zone are with low permeability. For this zone, there is an inverse relationship between carbonation and permeability.
In the northern zone, the carbonate content of Maykop deposits is less than that of the Cretaceous sediments and varies in a small interval, it is 17.5% only in the Garayazi area. In most cases, the porosity varies in the range of 20-26 5% in the studied areas, and with these values, the characteristics of the reservoir can be well characterized. Permeability was not very high, it is 20-70 $x10^{-15}$ m^2 only in Tuva area.
In the central zone, the deposits of the Upper Maykop and Chokrak horizons are characterized by low carbonate content and relatively high porosity and permeability.
Lower Pliocene deposits (PS) in South Gobustan are characterized by a high reservoir properties.
Based on the lithofacies analysis of the Shamakhi-Gobustan depression, the increase of the reservoir properties from the North zone to the South direction was determined.
The prospect of oil and gas in Shamakhi-Gobustan oil-gas-bearing region is related to Meso-Cenozoic deposits. Industrially important oil accumulations were identified in the sandy reservoirs of the PS, upper Maykop and Chokrak horizons, which were uncovered during drilling in separate areas in the southeastern and southwestern tectonic zones of the area.
Presence of oil and gas are noted in the Upper Cretaceous fractured limestone and marls, which are widespread in the northern zone. The density of these rocks varies in the range of 1.94-2.55 g/cm^3 along the northern zone. The Upper Cretaceous deposits are buried under the Paleogene deposits in a south-southwest direction.
Oil-filled formations and dolomites in the form of breccias lying in separate intervals along the section of the middle and upper Miocene in central Gobustan are of special interest. It should be

noted that the natural reservoirs for collecting oil and gas cummulatives in the section of the Meso-Cenozoic deposits are the terrigenous and carbonate reservoirs.
The sandy-siltstone reservoirs of Maykop suite and Chokrak horizon are oil-gas-bearing in Hajivalli, Umbaki, Maraza, Donguzlug areas. A short-duration oil flow was obtained in the upper Cretaceous fractured-carbonate reservoirs in Gizmeydan and Hilmilli areas.

Keywords: carbonation, porosity, permeability, reservoir, Maykop, Cretaceous, fractured-carbonate, core

I. İntroduction

The Shamakhi-Gobustan oil-gas-bearing region is a regional geostructural element. İt is located in the southwestern limb of the Greater Caucasus close to the crest part.

The region is surrounded by the following geotectonic elements from north to south: the southern part of Govdag depression (Northern Gobustan), Shamakhi, Central Gobustan, South-western, South-eastern Gobustan and Alat tectonic zone [1,2].

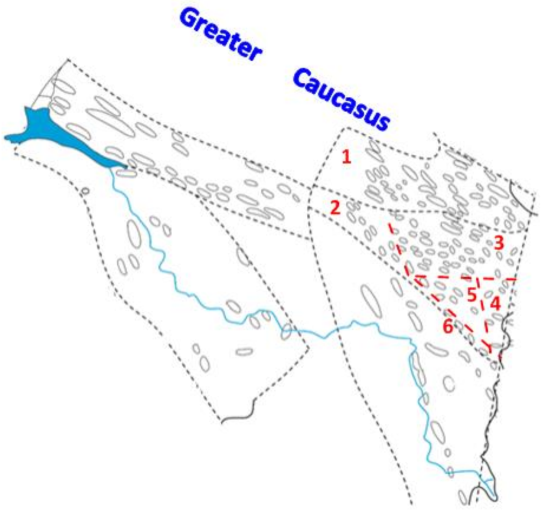

Figure 1: *Overview map of the tectonic zones of the Shamakhi-Gobustan oil-gas-bearing region*
Tectonic zones: 1- Northern Gobustan; 2- Shamakhi; 3 - Central Gobustan;
4 - South-eastern Gobustan; 5 - South-western Gobustan; 6 - Alat

In each geotectonic element, a number of regional anticlinal zones are separated, which are composed of a large range of stratigraphic sedimentary layers on the surface of the earth (from the lower Cretaceous in the north to the upper Pliocene in the south). The common characteristic of these zones is as follows. As a result of the ascent of the northern limbs and the descent of the southern limbs, the anticlines were bent to the south, the crests of the anticlines were complicated by longitudinal faults and mud volcanoes located on them. The dimensions of the folds depend on the lithological composition of the deposits that make them up. The widht of anticlines is 5-7 km made up by competent rocks and length is 13-15 km, while the anticlines made of soft rocks are 2 km widht and 10-5 km length [3].

Shamakhi-Gobustan oil-gas-bearing region is one of the most promising regions of Azerbaijan due to the hydrocarbon potential of Meso-Cenozoic deposits. Paleogene-Miocene deposits, which are widespread in the area, as well as Mesozoic and Pliocene deposits, are one of the main areas of exploration for discovering new oil and gas reserves [4].

The region has a complex geological structure and is relatively poorly studied. There are 79 local uplifts in this oil-gas-bearing region. In total, 5 oil and gas fields with a small reserves were discovered and put into operation in the Shamakhi-Gobustan oil-gas-bearing region, and oil and gas have been produced from these fields for a long time. These are East Hajiveli, Umbaki, Duvanni and Dashgil fields [5,6].

Only one structure- the Shikhigaya structure- was prepared for deep exploration drilling using the seismic exploration method.

Oil and gas occurrences and flows from Meso-Cenozoic deposits are optained. They are related with natural surface outcrops, as well as with fractured carbonate, sandy-siltstone reservoirs of drilled wells in the Shamakhi-Gobustan oil-gas-bearing region [7].

II. Metodology

The collected materials about of Meso-Cenozoic deposits show that these deposits are suffer of facies changes through the section vertically and areally along the horizontal in the Shamakhi-Gobustan oil-gas-bearing region. This is provide a basis for determining the distribution zones of reservoir rocks.

Reservoir properties of numerous core samples taken from Meso-Cenozoic deposits found in the research area were studied.

The oil-gas shows related to the Paleocene reservoirs in the separate uplifts of North Gobustan, formed from Mesozoic deposits, are mainly attributed to its southern part. Here, numerous thin (0.4-1.2 m) calcareous sandstone interlayers are found in the section of the Danian stage of Paleocene series (Ilkhidag suite).

Sand layers up to 10 m thick can be found in the section of the Sumgait suite (Paleocene) in the Garajuzlu and Nabur uplifts of the northern zone [8]. They are fine-grained and dense. Oil seeps are observed related with these sandstone layers in the Tuva area. The thickness of the sandy-clayey layer sometimes reaches 25 m, which is important as an oil object. The thickness of the Sumgait suite increases from the crest part of the folds towards its limbs and periclinals. An increase in the thickness of the sandstone layers is observed in this direction. This fact is also confirmed by the section of numerous structural wells drilled here. In the southern part of the northern zone, the thickness of medium- and coarse-grained sand and sandstone layers reaches 1.5-2 m in the section of the middle Govundag stage of the Eocene series. There is a sandy-clayey layer in the section of 25-30 m thick, which oil shows are found.

The lower and middle Eocene is 150-200 m thick in Central Gobustan and consists of irregular alternation of marly clays, marls, argillite and tuffaceous sandstones. The top of the Upper Eocene is 200 m thick in Cheyildag and is mainly composed of clays, while in Arzani-Kilij it consists of crushed clays [9,10].

In the southern part of the central zone of Gobustan, in the section of the Upper Eocene, intensive oil shows were noted in thin sandy layers (Boyanata, Baygustu, Boztepe).

All areas of Shamakhi-Gobustan are represented by clayey lithofacies of Lower Maykop.

The analysis of the prospecting-exploration works conducted in the South-West Gobustan area of Shamakhi-Gobustan depression shows that the oil and gas shows mentioned along the section are mainly observed in the Upper Maykop, Chokrak and Sarmatian reservoirs. As a result of drilling, intensive oil and gas flows were recorded in East Hajivalli and Gilij areas. Oil and gas deposits from the sandy-siltstone reservoirs of Upper Maykop and Chokrak were discovered in the Umbakı field. In South Gobustan, alongside the section of the Upper Maykop, numerous layers of sand and sandstone are found and their thickness increases toward south and southwest. In the Umbakı field, the horizon III of Maykop series is better studied by drilling and has more oil-gas-bearing [11].

III. Discussion and results

Analyzes of rock samples taken in Shamakhi-Gobustan oil-gas-bearing region were conducted to study the changes in reservoir properties of reservoirs of different ages.

In the Upper Cretaceous marl, sandy limestone rock samples in the Chikilchay area located in the northern zone, the carbonate content is 73-80%, the porosity is 14-26%, and the porosity is very low (2.5-3.0%) in the 2 samples with high carbonate content. The density of rocks is 2.3-2.44 g/cm^3.

In the Upper Cretaceous argillaceous marl samples in Eastern Agburun, carbonate content is 24-27%, porosity is 6.2-9.9%, permeability is 0.07x10^{-15} m^2, in Goradil area, marl samples of the same age have carbonate content of 60.5%, porosity is 6.3%, permeability 0.001x10^{-15} m^2, carbonate content in sandy-limestone samples is 57.6%, porosity is 8.1, permeability is 0.001x10^{-15} m^2, carbonate content in calcareous siltstone samples is 35%, porosity is 5.3%, permeability is 0.001x10^{-15} m^2, in the samples of limestone siltstone taken from Qizmeydan area, carbonate content varies from 27.3 to 93.4%, porosity from 2.9 to 17.8%, permeability from 0.001 to 1.5x10^{-15} m^2.

In the structure-mapping wells drilled in the Goradil area, gas and oil shows from the Upper Cretaceous deposits were observed. The Lower Cretaceous sandy carbonate reservoirs are considered to be more promising in this area. In separate wells (4, 5, 7) in the Garayazi area, active oil, gas, and water shows were recorded from the Upper Cretaceous deposits [12]. The oil and gas prospects of the area are mainly related to the Lower Cretaceous deposits. During the testing of structural-exploration well number of 36 in the Qizmeydan area, 3.5 t/day of light oil flow was obtained from sandstone and sandy limestone deposits of Upper Cretaceous series. Oil flow also was obtained from wells number of 15, 20, 29, 34 during the drilling process [13].

In Yunusdag area clayey limestone rock samples, carbonate content varies from 53.6 to 77.6%, porosity from 2.8 to 3.2%, permeability from 0.001x10^{-15} m^2 (Fıg.2). Weak gas-water shows were observed here in individual wells from Upper Cretaceous (Campanian, Maastrichtian) deposits. The main oil-gas object in the Yunusdag anticline is considered to be the Lower Cretaceous granular carbonate reservoirs.

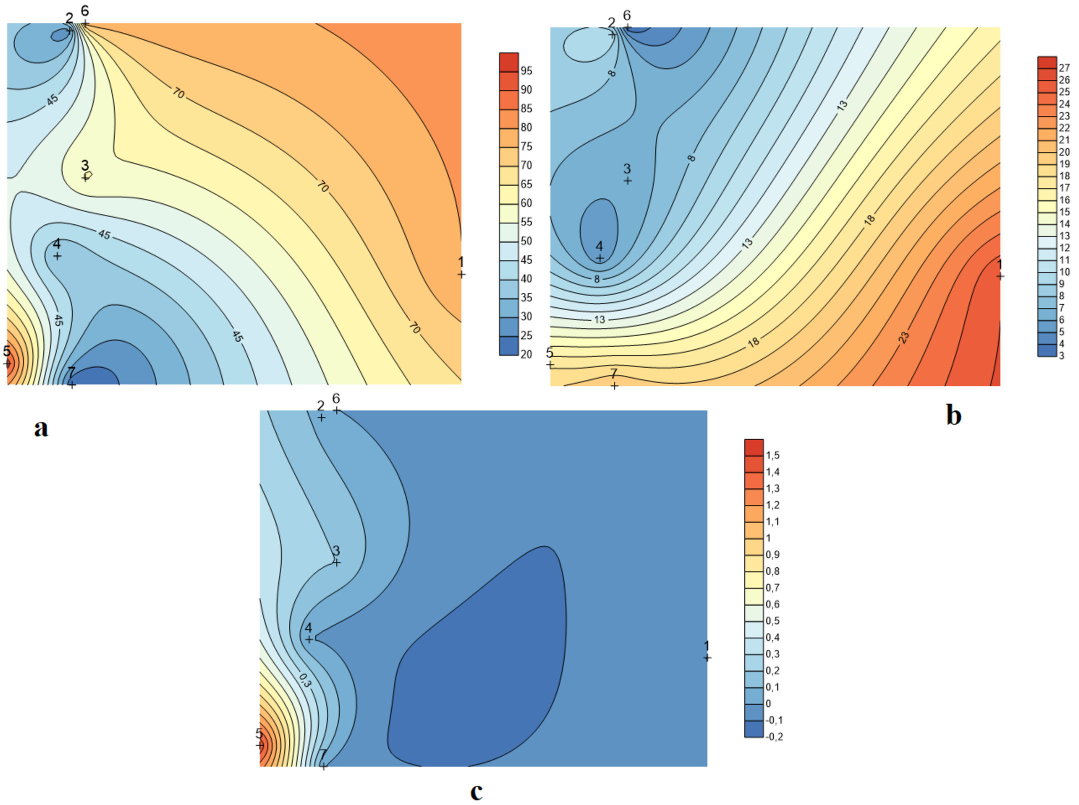

Figure 2: *Carbonate content (a), porosity (b), permeability (c) maps of Upper Cretaceous deposits in the northern zone of the Shamakhi-Gobustan depression*

Areas: 1 - Chigilchay; 2 - Shargi Agburun; 3 - Goradil; 4 - Garayazi; 5 - Gizmeydan; 6 - Yunusdag; 7 - Angikharan

In the Goradil area, located in the northern zone, the carbonate content of Eocene age silty limestone samples is 65.4%, porosity is 7.6%, permeability is 0.001x10^{-15} m^2, Calcareous siltstone samples of Miocene are characterized by the carbonate content of 37.4%, porosity is 15.3%, permeability is 0.001x10^{-15} m^2 , carbonate content in argillite samples of Maykop is 13.5%, porosity is 13.8%, permeability is 0.001x10^{-15} m^2, porosity is 20% in Maykop age clay samples in Agburun area, permeability is 0.001x10^{-15} m^2, porosity in Paleocene age clay samples in Yunusdag area is 13-28% , Eocene age limestone, marl samples have a porosity of 14%.

Carbonate content in siltstone limestones of Maykop agedeposits in Garayazi area is 17%, porosity is 12.7%, permeability is 0.001x10^{-15} m^2, carbonate (8.5-9.0%) in samples of Maykop-age limestone, marl, siltstone, clayey limestone in Gizmeydan area it varies in a small interval (1.7-3.5%).

In the Tuva area of Northern Gobustan (Fig.3), there are numerous oil and gas shows related to Upper Cretaceous deposits, some of which are related to faults. During drilling process of structure-mapping wells number of 2 and 5, oil and gas shows were obtained from deposits of the Paleocene and Danian stages. The drilling process of exploration well number of 1, gas shows was observed at a depth of 113 (Danian)-2219 m (Santonian) [14]. During the passing of the deposits of the Campanian stage in the exploratory well number of 2, gas shows was determined. Despite this, the prospect of industrially important oil and gas deposits is considered to be granular reservoirs of the Lower Cretaceous series. Study results of rock samples taken from well number of 1 show that Paleocene sandstones are light oil-saturated. Their porosity is 15.5-22%, effective porosity is 1.0-2.5%, and permeability is 20-70x10^{-15} m^2.

Oil and gas shows are noted along the section of fractured limestone and marls of Upper Cretaceous buried under Paleogene sediments toward south-southwest in the northern tectonic zone. Based on the analysis of rock samples, it should be noted that these deposits lithologically have favorable reservoir properties.

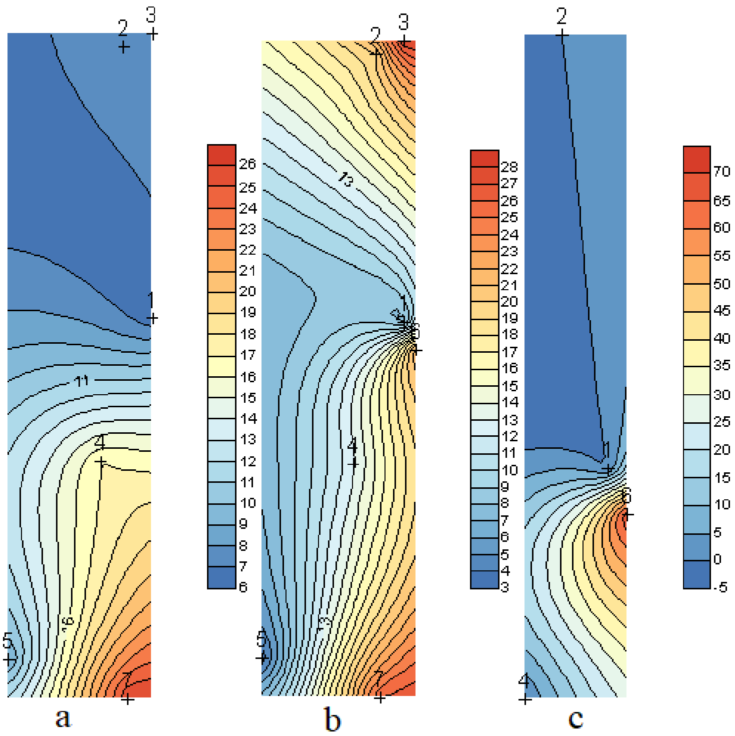

Figure 3: *Carbonate content (a), porosity (b), permeability (c) maps of Paleogene-Miocene deposits in the northern zone of the Shamakhi-Gobustan depression*

Areas: 1- Goradil ; 2-Shargi Agburun; 3- Yunusdag; 4-Garayazi; 5-Gizmeydan; 6-Tuva; 7-Angikharan

Sandy and sandstone layers of Middle Eocene series alongside the south part of the northern zone, represented by reservoir properties with porosity of 17-24%, effective porosity of 2.5-3.5% and permeability of 35-70.0x10^{-15} m^2.

The average carbonate content of the Lower Maykop deposits in the Cheyildag area is 8.0%, the total porosity is 20.5%, the effective porosity is 3.4%, and the permeability is $72.0x10^{-15}$ m^2. These indicators are 6.9%, 15.6% and $22.0x10^{-15}$ m^2 in the Umbaki area, respectively (Fig.4).

In the Maraza area located in the central zone of Gobustan, carbonate content of siltstone limestone, marl deposits of Upper Cretaceous is 23.2-65.3%, porosity is 3.9-17.6%, permeability is $0.001x10^{-15}$ m^2, the carbonate content of sandy limestones of Paleocene is 68-76.4 %, porosity 12.6%, permeability $0.3\text{-}0.6x10^{-15}$ m^2, carbonate content of clayey marls of Maykop series is 2.5-28%, porosity is 7.5-24.4%, and permeability is $0.001x10^{-15}$ m^2, limestone, silty limestone, and sandy limestones of Upper Miocene represented by carbonate content of 45.4-93.4%, porosity is 14.3-21.3%, permeability is $0.2\text{-}10.1x10^{-15}$ m^2. Here, the Upper Miocene deposits are characterized with high porosity and permeability.

The lithofacies characteristics of the Upper Eocene sediments show that these sediments in the Bayguştu area have a higher sand content. This suggests that the collector characteristic is higher in that area.

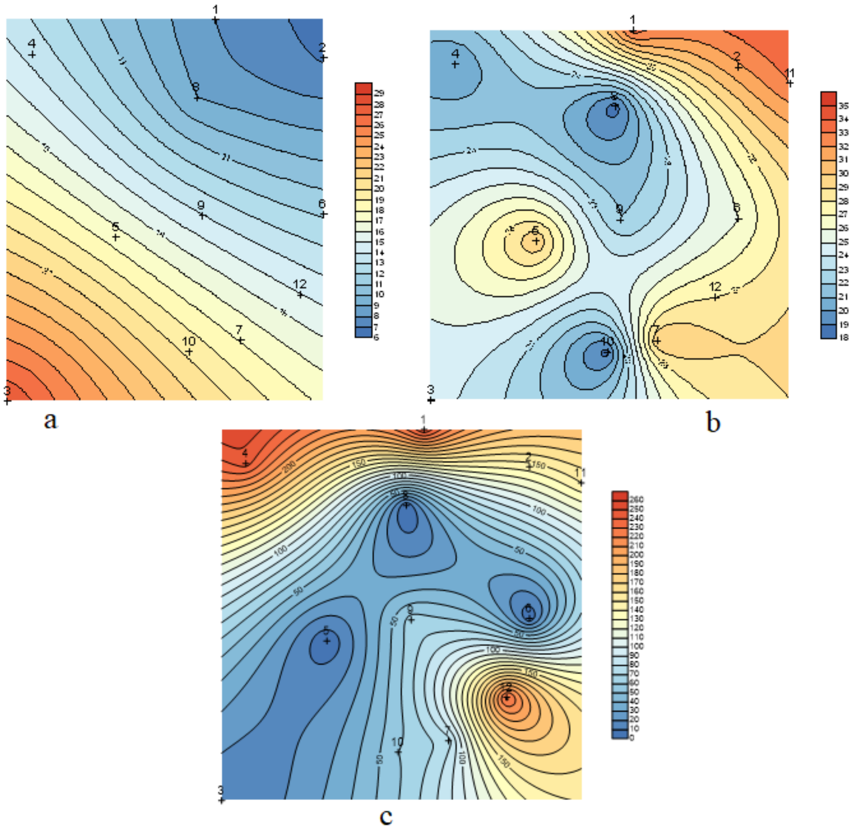

Figure 4: *Carbonate content (a), porosity (b), permeability (c) maps of Upper Maykop deposits in the central zone of the Shamakhi-Gobustan depression*

Areas: 1- Cheyildag ; 2-Umbaki; 3- Maraza; 4-Baygushtu; 5-Shaytanud; 6-Hajiveli; 7-Sundu; 8-Nardaran-Suleyman; 9-Nardaran-Akhtarma; 10-Gijakiakhtarma; 11-Arzani-Gilij; 12-Ilkhichi

The sandy layers forming the horizon are characterized by high collecting properties. The total porosity of the rocks is 20% on average, the effective porosity is 6% on average, and the permeability is 245x10-3 μm2.

The porosity of Upper Cretaceous sediments in the Angikharan area is 6-20%, the porosity of Paleocene sediments is 8-10%, the porosity of Eocene sediments is 10-26%, and the porosity of Miocene sediments varies from 6-10%. The density of the rocks of the mentioned stratigraphic units varies in the range of 2-2.6 g/cm3. In the Angikharan field, natural oil output is noted in the valleys intersecting with the southeastern pericline of the fold, and the oil-gas prospect is related to Upper Cretaceous carbonate and Lower Cretaceous terrigenous reservoirs, which increase in thickness from north to south, in the direction of regional subsidence of Mesozoic sediments.

The porosity of the rocks of Upper Maykop in Shaytanud area is 20-30%, permeability is 1.5x10^{-15} m^2, density is 2.1-2.18 g/cm^3. Here, the same name mud volcano is located. Around of Shaytabud mud volcano there are numerous mud gryphons and mud salsas. Gas, water, and water with an oil films are released from them. The Upper Maykop series represents with alternation of sand, sandstones and clays that along the section gas shows are observed. Thick sandy-clay bands saturated with oil were uncovered in the Maykop section. Slight oil and gas shows were noted along sandy-clay bands of Upper Maykop uncovered at different depths by structure-mapping wells [7,15]. The prospect in the lowered southern limb of the Shaytanud area is related to the Maykop suite. The Upper Cretaceous carbonate reservoirs are considered promising also.

In Hajiveli area, porosity of deposits is 21-26%, permeability is 1.5x10^{-15} m^2, density is 1.92-2.08 g/cm^3. Here, oil and gas shows were observed in the structure-mapping wells drilled into Upper Matkop and Chokrak horizons (middle Miocene) [16]. Oil and gas prospects are related with sandy deposits of Oligocene, Lower-Middle Miocene and carbonate reservoirs of Upper Cretaceous (Fig.5).

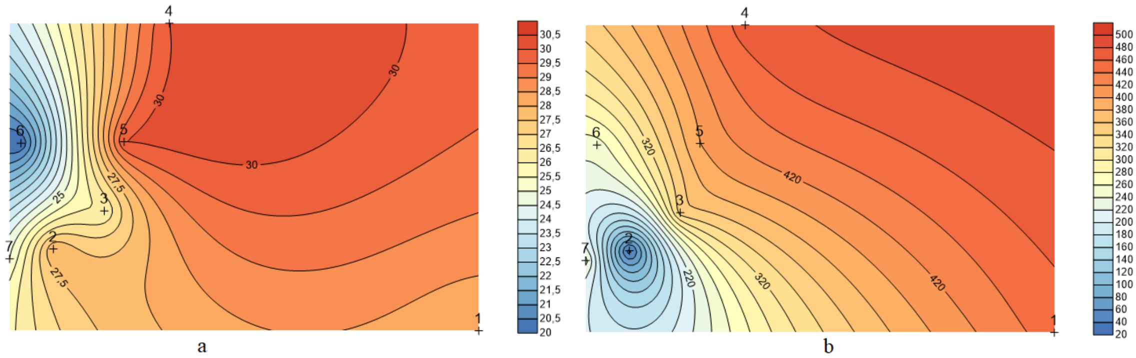

Figure 5: *Porosity (a), permeability (b) maps of Chokrak (Middle Miocene) deposits in the central zone of the Shamakhi-Gobustan depression*

Areas: 1-Cheyildag; 2-Sundu; 3-Ilkhichi; 4-Arzani-Gilij; 5-Shargi Hajiveli; 6-Nardaranakhtarma; 7-Gijaki.

The porosity is 18.0-30%, permeability varies in the range of 25-75x 10^{-15} m^2 in the Sundu area. In the structure-mapping wells in the Western Sundu area, oil flow related to the Upper Maykop, Chokrak, Karagan deposits was observed. In particular, a gas gush was obtained in well number of 10 from the sandy bands located in the upper part of the Chokrak horizon [7]. The oil and gas prospects of the area are related to the Maykop, Chokrak horizon, and the main object for the search of industrially important oil and gas deposits is the carbonate reservoirs of the Upper Cretaceous.

The argillites of Maykop series are represented by a carbonate content of 9%, porosity of 18.5%, permeability of 0.001x10^{-15} m^2 in the Nardaran-Süleyman area. In the process of drilling structure-mapping wells, intense oil and gas shows were noted from sandy reservoirs of the Upper Maykop, Chokrak horizon [9]. İn addition, Upper Cretaceous carbonate reservoirs are also considered the main object for the search of industrially important oil deposits.

Porosity of reservoirs in the Nardaran-Akhtarma area is 10.0-22%, permeability is 18-65x$10^{-15}$$m^2$, in the Gijakiakhtarma area porosity is 11.0-18.6%, permeability is 15-60x10^{-15} m^2, in Cheyildag porosity and permeability is 13.5-33.5% and 35-250x10^{-15} m^2, in Umbaki- is 11.5-31.8% and 10-145x10^{-15} m2, in Arzani-Gilij- is 12-33.0% and 30-150x10^{-15} m2, in Ilkhichi- is 9.7-28.0% and 25-235 x10^{-15} m^2, respectively.

Oil-gas shows in the Nardaranakhtarma area are related to the Nardaranakhtarma mud volcano, numerous mud gryphons, salsas, as well as the outcrops of sandy layers of the Upper Maykop at the crest and Chokrak horizon deposits along the south limb of the fold. Oil-gas shows related to the deposits of the Maykop suite and Chokrak horizon were also observed during the drilling of exploration and structure-mapping wells [9].

The Gijakiakhtarma area is differ by the presence of various oil and gas shows. İn addition, information about oil and gas content of Maykop, Chokrak deposits was obtained through structure-mapping wells. Also, during the opening of the deposits of the Karagan (Middle Miocene) horizon, Pontian (Upper Miocene) and Aghjagil (Upper Pliocene) stages near the tectonic fault, slight oil and gas shows were noted [5]. The presence of 1.5-2 m thick sandy layers in the section of the Upper Maykop and Chokrak horizons allows to consider it as the main object for the search of oil and gas induvidual deposits. The main object of exploration is the carbonate reservoirs of Upper Cretaceous.

Chokrak horizon is represented by sandy-clay facies in South Gobustan. Sandy layers reach their maximum in Cheyildag, Umbaki, and East Hajivalli areas. An industrially important oil deposit has been uncovered in the horizon I of the Çokrak stage of Umbaki field. Along the section of Chokrak with high porosity reservoir rocks oil and gas shows were recorded in exploration wells number of 9, 12, 29, 32 in Cheyildagh area. The production of the wells varies between 2.5 t/day. The layers are traced to the Zahirdag area and an oil gush was obtained from the section of Chokrak at a depth of 529 m in the exploration well number of 9. Oil-bearing layers of Chokrak stage belong to the southern limb of the Cheyildag uplift in the Cheyildara area. 6 oil-filled sandy layers are noted along the section [8]. The porosity of the rocks here is 26-28%, permeability is 100-450 $x10^{-15}$ m^2.

There is a sandy sandstone layer 45-55 m thick, 100 m below the top of the Chokrak horizon in the Sundu area. A gas gush was noted in well number of 10 from this layer [6]. The porosity of the rocks is 24-28%, and the permeability is 24-27 $x10^{-15}$ m^2.

Natural oil-gas shows in Ilkhichi and Arzani-Gilij areas are related to mud gryphons, and mud salsas of mud volcanoes. İnrush of gas and oil were observed from the sandy layers of Chokrak. Also, intense oil-gas shows were observed during the passing of individual sandy layers of Maykop, Miocene, Productive series (Lower Pliocene). The gush of gas obtained from Sarmatian, Konk and Karagan sandy bands has a special interest [14]. Apart from these deposits, carbonate reservoirs of Upper Cretaceous are also considered promising. The porosity of the rocks of the Chokrak horizon is 22-26%-24-30%, and the permeability is 30-350-50-470 $x10^{-15}$ m^2.

Oil-gas-bearing of the sand-sandstone layers of the Chokrak horizon in Eastern Hajivalli area has been confirmed. 5-7 t/day of heavy oil flow was obtained during the testing of sandy layers of the Chokrak horizon in 2 wells [9]. The porosity of the rocks is 25-30%, and the permeability is 100-400 $x10^{-15}$ m^2.

Fine-grained sands of Chokrak in the Nardaranakhtarma area are oil-gas-bearing. 2 oil-bearing layers are identified in the Chokrak stage along the northern limb. Layer I is located 115 m below the top of the horizon and is represented by fine- and medium-grained sands. Layer II is located 166 m below the top of the horizon. This is the main oil-bearing layer in the northeast limb and it is clearly traced. The porosity of the rocks is 13.8-20%, permeability is 25-250 $x10^{-15}$ m^2.

Oil leaks from the dolomites of the Çokrak horizon were noted in Gicaki area [10]. The porosity of the rocks is 21-25%, the permeability is 28-250 $x10^{-15}$ m^2.

Rock samples analyzes prevail taken from the Productive series (PS) in South Gobustan.

The porosity of the sandstones of the PS in Solakhay area is 11.4-26.5%, permeability is 90-664 $x10^{-15}$ m^2. In the southwestern limb of the structure, there are several small faults are found, which are associated with a large number of mud gryphons, mud salsas, which inrush of oil, gas, and water [7, 17, 18] (Fig.6). Intensive oil and gas shows were noted during the testing of almost all exploratory wells during the drilling process. There was an oil gush with production of 5-7 t/day in separate wells. 4 sandy horizons (I, II, III, IV) with a thickness of 900 m, three of which are oil-bearing, have been determined in the unopened part of the PS [9].

Carbonate content of sandy-clayey-limy deposits of PS in Dashgil area is 3.5-24.7%, porosity is 6-35.8%, permeability is 26-221 $x10^{-15}$ m^2.

There are numerous natural oil and gas shows in the Dashgil area relation to the activity mud gryphons of the Dashgil mud volcano. Oil and gas shows have also been recorded in numerous structure-mapping and exploratory wells related to the sandy-siltstone horizons of the PS. During the testing of the horizon VII of the PS in the southern limb of the fold, an industrial oil flow with an initial production of 75-100 t/day was obtained from well number of 15 [10].

The porosity of sandy deposits of PS in the Anart area is 20.2-30.6%, permeability is 32-326 $x10^{-15}$ m^2.

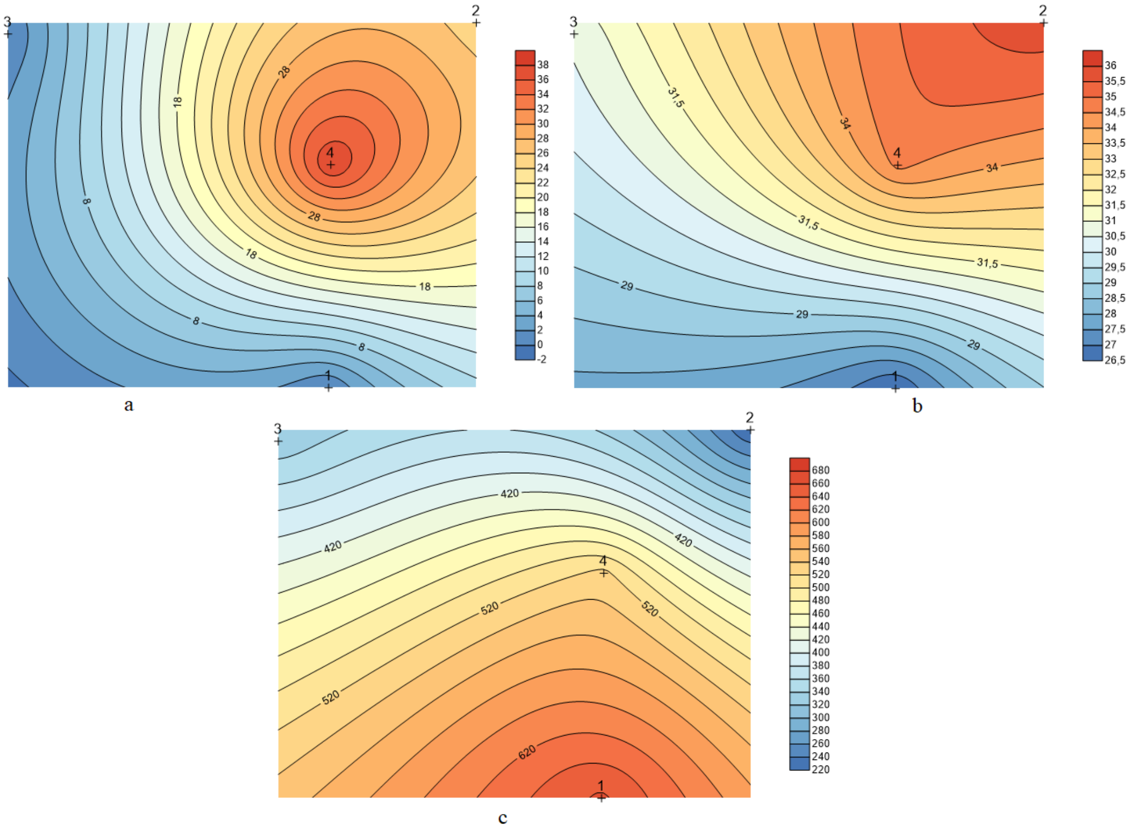

Figure 6: *Carbonate content (a), porosity (b), permeability (c) maps of PS (Lower Pliocene) deposits in the South Gobustan*

Areas: 1-Solakhay; 2-Dashgil; 3-Anart; 4-Duvvani.

İn addition, along the section of the PS 9 single sandy horizons were separated, from which 50,000-75,000 m^3/day of industrial gas flow was obtained. During the testing of one of the sandy horizons, a gas gush was obtained from well number of 6 with a flow of 110,000 m^3/day [6]. This is suggests that the Anart field is promising as a gas facility. By outlining the open gas field in the intersection of the PS, conducting exploration work in the unopened part of the PS, it is possible to open an analogue of the V horizon of the PS in the Garadag gas and oil field.

Carbonate of Miocene clayey-siltstones in Duvanni field is 2.7-44.1%, permeability is 11.3-36x$10^{-15}$$m^2$, carbonation of sandy-clayey-siltstone sediments of PS is 5.2-38%, porosity is 7.0-34.64 %, permeability varies in the range of 11.7-526 x10^{-15} m^2.

Industrially significant gas content of 2 sandy horizons was determined with the first exploratory well in the Duvanni field. The industrially important induvidual gas deposit related to the reservoirs of the horizon V covers the small northwestern part of the structure, and the large gas-condensate deposit related to the sandy-siltstone reservoirs of the horizon VII covers the southeastern half of the fold [6].

The prospecting for new oil and gas deposits in the Duvanni field may be related to the sandy-clayey sediments of the Maykop (Oligocene-Lower Miocene) suite, which was determined based on the analysis of eruption products of mud volcanoes.

As the Shamakhi-Gobustan depression is located in the area of the southwest limb of the Greater Caucasus, which is relatively close to the crest, the compressive stresses generated in this mountain folding system are intensely reflected here and have led to the development of thrusts, napps and mud volcanism in its structure. Due to the lithofacies composition of the rocks, this situation also affects the formation of derivative reservoir properties in them [11]. The northern tectonic zone of the Shamakhi-Gobustan depression is characterized by a wide spread of Cretaceous deposits (thickness 2000-2500 m), and mainly competent terrigenous-carbonate deposits were formed here. These rocks have a highly derived reservoir property.

Paleogene-Miocene-Pliocene deposits are widespread in the Central and South-West, South-East tectonic zones and have been relatively studied by drilling. It is noted that the number and thickness of the sandy-siltstone layers involved in their intersection increases from north to south-southeast.

It should be noted that the increase in the thickness of the deposits of Maykop, Chokrak and PS in the southern direction and the presence of sufficiently thick sandy reservoir horizons in their composition also played a role in the separation of South Gobustan as a highly prospective zone.

The prospect of oil-gas-bearing in Shamakhi-Gobustan region is related to Meso-Cenozoic deposits. Industrially important oil accumulations were identified in the sandy reservoirs of the PS, Upper Maykop and Chokrak horizons, which were uncovered during drilling in separate areas in the southeastern and southwestern tectonic zones of the area.

The oil and gas shows are noted in the Upper Cretaceous fractured limestone and marls, which are widespread in the Northern zone. The density of these rocks varies in the range of 1.94-2.55 g/cm^3 in the northern zone. The Upper Cretaceous sediments are buried under Paleogene sediments in the south-southwest direction [1].

Oil-filled layers and dolomites in the form of breccias lying in separate intervals at the section of the Middle and Upper Miocene in central Gobustan are of special interest. It should be noted that terrigenous and carbonate reservoirs are natural reservoirs for collecting oil and gas deposits in the Meso-Cenozoic deposits.

The sandy-siltstone reservoirs of Maykop suite and Chokrak horizon are oil-gas-bearing in Hajivalli, Umbaki, Maraza, Donguzlug areas. A short-duration oil flow was obtained in the upper Cretaceous fractured-carbonate reservoirs in Gizmeydan and Hilmilli areas.

IV. Conclusion

1. Due to incease the number and thickness of the sandy interlayers along the section of the Upper Cretaceous from the northern zone to the south, that is, in the direction of the regional dip, so they can be considered promising in the Central Gobustan zone in the Shamakhi-Gobustan depression.

2. In the northeastern part of South-Eastern Gobustan, the sediments of the Maykop suite and the Chokrak horizon have a high reservoir properties, and they are likely to contain industrially important oil and gas.

3. Based on the analysis of the reservoir properties of the rocks, it was determined that there are oil-gas sandy-siltstone reservoirs with high reservoir properties in the upper half-layer of the Maykop suite, the Chokrak horizon and the Sarmatian stage deposits in South-Western Gobustan.

4. The sandy horizons of the Upper Maykop series are considered most promising In the authochthones of the overthust that complicate the large folds in South-West Gobustan.

Abstract

The article discusses rheological models of non-Newtonian oils, and also analyzes existing theories on reducing hydraulic resistance when using anti-turbulence additives, the main methods and approaches to transporting high-viscosity oil. High-viscosity oil from the North Komsomolskoye field, as well as anti-turbulence additives from the Monomer company, were used as the object of study. As a result of processing the results of experimental studies, the rheological model of oil was determined, and the effectiveness of using anti-turbulence additives from the Monomer company for this oil was established. The work also carried out a comparative analysis of the existing dependencies of the hydraulic resistance coefficient, compared the main dependencies and found that the most accurate models are those based on the universal law of resistance and the Altschul logarithmic formula, taking into account the Deborah number and the model for calculating efficiency through the value.

Keywords: highly viscous oil; heavy oil; additives; transport; coefficient of hydraulic resistance; reserves of high-viscosity oil; Toms effect.

I. Introduction

Currently, reserves of light, low-viscosity oil are being depleted. This fact poses an urgent task for companies in the fuel and energy complex involved in drilling wells, field development and transportation, to study and resolve the issue of the economic feasibility of using heavy, highly viscous oils. In practice, this issue is fraught with enormous technical difficulties, ranging from the extraction of such oil to its refining [45].

Transportation of high-viscosity oil is one of the key challenges facing the modern oil industry. Due to its special rheological properties, such oil creates serious difficulties for engineers and technologists: its viscosity makes it difficult to move through pipelines, increases energy costs for pumping and contributes to equipment wear [1-3].

Currently, there are several main methods of transporting non-Newtonian oils: "hot" pumping, electric heating, hydropumping of high-viscosity oil, transporting oil with diluents, adding depressants and anti-turbulence additives to oil. Currently, one of the developing methods of oil transport is the transport of oil with anti-turbulence additives. This type of additives allows you to reduce hydraulic resistance during fluid movement; they can significantly change the physical and chemical properties of oil, improving its fluidity and reducing viscosity.

The principle of operation of anti-turbulence additives is based on the Toms effect. The Toms effect was discovered in the 1940s and has since been widely used in the oil industry. The essence of this phenomenon is that when a small amount of polymers is added to a liquid, its flow becomes more orderly, which reduces friction and facilitates the movement of liquid through the pipeline. This is especially true for highly viscous oil, which, without the use of additives, moves with high energy consumption. Additives that cause the Toms effect facilitate its movement through pipelines by changing the flow structure. As a result, the speed of oil movement increases and the energy consumption of the pumping process decreases.

The use of PTP also makes it possible to use the pipeline network more flexibly - to expand bottlenecks, replenish the volume of supplies after forced downtime, respond to changes in the viscosity of the pumped oil, to a shortage of electricity in a particular area, to changes in oil prices on the market.

The presence of turbulent flow is one of the necessary conditions for the operation of the PTP. Therefore, for heavy oils with high viscosity values, which are transported in laminar mode, the use of PTP will not lead to an increase in productivity. However, for oils with a viscosity of the order of several hundred centistokes, the use of PTP is possible; it is also possible to use PTP for heated oils or when pumping with a diluent, when a turbulent regime is realized.

Anti-turbulence additives can be divided into 3 types: polymers, fibers and surfactants.

The shares of drug consumption by region are distributed as follows: North America – 54.2%, Europe – 9.0%, Middle East – 13.1%, Southeast Asia – 4.4%, Africa – 11.7%, Countries CIS – 4.0%, China – 3.7%.

For the first time on an industrial scale, PTPs were tested in 1979 on the Trans-Alaska main oil pipeline with a diameter of 1219 mm by the company in order to increase the throughput of the oil pipeline. In 1978, TAPS conducted a very thorough laboratory study of the process of producing polymers in order to improve their characteristics. As a result, a polymer additive was developed, which was named CDR-101 and began to be used in the company’s pipelines. In 1980, a number of changes were made to the polymerization process, which led to the creation of a new high-performance polymer additive CDR-102. Within two years of using CDR-102 additives from Conoco Specialty Products Inc, the pipeline capacity was increased from 16 to 32 thousand m^3/day [4-5].

The world's leading manufacturers, as a rule, have a wide range of additive brands designed for various types of pumped products. The main producers on the global DTP market (80-90%) are foreign companies ConocoPhillips (USA) and Baker Hughes (USA).

Based on the results achieved, these companies have developed a line of PTP specifically for heavy oil based on polar polymers that have the ability to dissolve in the presence of a high content of asphaltenes.

There are also several small producers on the market, for example, FlowChem (USA), Propipe (Spain, USA), Champion (UK, Netherlands) and the Chinese company China National Petroleum Co., which, as a rule, have a local business.

II. Materials and Methods

2.1. Reological models

Rheological models are used to describe the behavior of non-Newtonian fluids, that is, fluids whose dynamic (or effective) viscosity depends on shear stress and is not a constant value. Some of the most common rheological models for non-Newtonian fluids are: The Shvedov-Bingham model is used to describe liquids that have an initial yield strength τ0, below which it does not flow and has the properties of a solid.

The Shvedov-Bing equation has the form:

$$\tau = \tau_0 + \eta \cdot \dot{\gamma} \quad (1)$$

where τ - shear stress, η - viscosity coefficient, γ - shear rate.

The Ostwald-de Waele model is a generalization of Newton's law of viscosity and describes, for example, the flow of polymer solutions. In this model, viscosity varies proportionally to the degree of strain rate:

$$\tau = K \cdot \dot{\gamma}^n \quad (2)$$

where K - model parameter, n is an index that determines the degree of nonlinearity.

The Herschel-Bulkley model is used to describe thixotropic liquids. In this model, shear stress is represented by the equation:

$$\tau = \tau_0 + K \cdot \dot{\gamma}^n \quad (3)$$

The Casson model is used to describe pseudoplastic fluids, in which the viscosity decreases with increasing shear stress, and has the form:

$$\tau^{\frac{1}{2}} = \tau_c^{\frac{1}{2}} + \eta_c^{\frac{1}{2}} \cdot \dot{\gamma}^{\frac{1}{2}} \quad (4)$$

where $\tau_c^{\frac{1}{2}}$ is Casson yield stress, η_c is Casson plastic viscosity.

The Prandtl model is used to describe the behavior of viscoelastic materials and has the following form:

$$\tau = arscin\left(\frac{\dot{\gamma}}{B}\right) \quad (5)$$

The Cisco model is used as a rheological model of pseudoplastic fluids and has the form:

$$\tau = \eta_\infty \cdot \dot{\gamma} + \eta \cdot \dot{\gamma}^n \quad (6)$$

To take into account the nonlinearity of changes in shear stress with increasing shear rate in non-Newtonian fluids, Williamson and Gillespie proposed introducing a special correction factor:

$$\eta = \frac{\tau_0}{\dot{\gamma} + \chi} + \eta_\infty \quad (7)$$

The Cross model is considered a transformation of the previous model and is quite universal for describing the behavior of viscous liquids:

$$\eta = \frac{(\eta_0 - \eta_\infty)}{\left(1 + \frac{\dot{\gamma}}{\chi}\right)} + \eta_\infty \quad (8)$$

The Carreau model is used to describe the behavior of nonlinear viscous media in isothermal and non-isothermal processes and takes into account the thixotropic properties of the liquid being studied:

$$\eta = (\eta_0 - \eta_\infty)(1 + (\lambda\dot{\gamma})^2)^{\frac{n-1}{2}} + \eta_\infty \quad (9)$$

There is also a modified Carreau-Yasuda model, which is used to describe dispersed and polymer systems and has the form:

$$\eta = \frac{\tau_0}{(\dot{\gamma}^n + \chi)^m} + \eta_\infty \quad (10)$$

To describe a viscous liquid containing dispersed particles, the Ree-Eyring model is used:

$$\eta = (\eta_0 - \eta_\infty)\frac{arcsh(\beta\dot{\gamma})}{\beta\dot{\gamma}} + \eta_\infty \quad (11)$$

The Rayner-Rivlin model is used to describe a rheologically complex viscous fluid:

$$\dot{\gamma} = \sum_{n=0} a_{2n} \cdot \tau^{2n+1} \quad (12)$$

There are a large number of rheological models that describe the behavior of non-Newtonian fluids. By transforming some of them, it is possible to obtain others, but analysis shows that there is no universal way to describe the behavior of a non-Newtonian fluid.

2.2. Hypotheses about the mechanism for reducing hydraulic resistance when using polymer additives

Polymer additives are one of the most effective means of reducing hydraulic resistance when transporting high-viscosity oil. Currently, there are several main hypotheses explaining the mechanism of their action.

The first hypothesis suggests that the polymers form a thin layer on the inner walls of the pipeline that acts as a kind of “lubricant” reducing friction between the pipe walls and the flow of oil.

The second hypothesis is related to changes in the structure of oil flow under the influence of polymers. It is assumed that polymers are able to “destroy” turbulence in a flow, turning it from turbulent to laminar or transitional. This also leads to a reduction in friction and, accordingly, hydraulic resistance.

The third hypothesis is the possibility of changing the physical and chemical properties of the oil itself under the influence of polymers, which can lead to a change in its viscosity and density.

These hypotheses are not mutually exclusive and may operate simultaneously. Table 1 summarizes the above, as well as other existing hypotheses about the nature of the reduction in hydraulic resistance when using polymer additives. The hypotheses are grouped according to the key features of the proposed mechanism of resistance reduction.

Table 1: *Hypotheses about the mechanism for reducing hydraulic resistance when using polymer additives*

Theory	Brief description
Molecular stretch	Turbulent flow, mixing with the polymer, deforms it. The influence of polymers on viscosity is significant, so the vortex is damped. This leads to excess local viscosity and energy dissipation [6-8]. These ideas were developed in work, where the stretching of macromolecules is accompanied by an increase in rigidity in the direction of stretching, which leads, in turn, to a significant increase in longitudinal viscosity. As the longitudinal viscosity increases, the formation of large-scale vortices and emissions in the near-wall region is inhibited.
Reduced turbulence generation	Some researchers [9-11] believe that polymer additives prevent the onset of turbulence and the effect of reducing drag is associated not with the dissipation of vortex energy, but with the suppression of their generation. However, it is possible that both mechanisms take place simultaneously.
Reduced turbulent dissipation	Some researchers [12-15] believe that polymer additives prevent the onset of turbulence and the effect of reducing drag is associated not with the dissipation of vortex energy, but with the suppression of their generation. However, it is possible that both mechanisms take place simultaneously.
Vortex stretching	It is postulated that the tensile resistance of the vortices reduces mixing and energy loss. Dilute polymer solutions can have longitudinal viscosities that are up to a thousand times higher than the steady-state viscosities, which can influence the drag reduction mechanism. The authors of the work [16-18] believe that the destruction of the vortex occurs as a result of the destruction of macromolecules due to energy absorption.
Anisotropic properties and turbulence	In a turbulent flow regime, the additive polymers are stretched in the direction of the flow. Uneven absorption of flow energy occurs and leads to anisotropy of turbulent transfer. Viscosity increases as turbulent

	movement occurs along the normal to the wall of the pipes, and as a result, the intensity of velocity pulsations normal to the wall decreases [19-21].
Laminarization of turbulent flow	Turbulence involves the waste of energy through the formation of tiny vortices, which leads to increased drag. Therefore, the reduction in resistance is a measure of flow laminarization.
Pseudoplasticity	It is assumed that the near-wall layer, due to pseudoplasticity (a decrease in viscosity under the influence of shear), may have a lower friction coefficient than that of a pure solvent. The theory was not developed, since a decrease in viscosity under the influence of shear, although it occurs, is by a smaller amount than the decrease in resistance [22-25].
Viscoelasticity and normal stresses	Polymer solutions exhibit viscoelasticity and normal stress differences, but at concentrations much higher than those required to reduce resistance. Very dilute solutions have no measurable elasticity and do not differ in viscosity from pure solvents. On the other hand, viscoelastic solutions of chemically cross-linked polyacrylic acid do not exhibit a resistance-reducing effect, although they exhibit pseudoplasticity. Thus, viscoelasticity is not a necessary condition for drag reduction.
Formation of supramolecular agglomerates	This theory implies a decrease in resistance when conditions are realized in a turbulent flow for intermolecular interaction, while in a static state, dilute mixtures of polymers remain molecularly dispersed.

The presence of several theories indicates the absence of a single mechanism for reducing hydraulic resistance using anti-turbulence additives.

The lack of a unified theory entails different approaches to applied calculations for determining the Toms effect and calculating the efficiency of reducing hydraulic resistance (calculating the coefficient of hydraulic resistance when using PTP) depending on different flow conditions.

2.3 Analysis of dependencies to determine the coefficient of hydraulic resistance using PTP

In world practice, there are many different models for calculating the coefficient of hydraulic resistance in a mixture with additives and criteria describing the effectiveness of the additive.

However, most of them were derived from studying the Toms effect in aqueous solutions.

One of the main and classic universal models is the model proposed by A.D. Altshul [26-28]:

$$\frac{1}{\sqrt{\lambda}} = 1{,}8 \cdot \lg\left[\frac{Re_0}{Re_0 \frac{0{,}1 \cdot k_э}{D} + 7}\right] \quad (13)$$

where λ – coefficient of hydraulic resistance for flow using an additive; Re_0 is the Reynolds number without adding an additive.

Another model for calculating the hydraulic resistance coefficient using anti-turbulence additives in an oil flow is a model that takes into account the Deborah number:

$$\lambda = \frac{\lambda_0}{(1 + De^2)^m} \quad (14)$$

where m – the Leibenzone coefficient.

The Deborah number is determined by the following equation:

$$De = \alpha_0 \theta^{\alpha_1} Re_0^{\alpha_2} \quad (15)$$

where θ – additive concentration, g/t; α_0, α_1, α_2– empirical coefficients.

The Reynolds number in this case is:

$$Re = Re_0(1 + De^2) \quad (16)$$

In the work of the authors [29-32], based on experiments with additives, the following model for calculating the hydraulic resistance coefficient is proposed:

$$\lambda = 0{,}11\left(\frac{Z + \varepsilon + X^{1{,}4}}{115X + Y + 1}\right)^{0{,}25} \quad (17)$$

where ε – elative roughness of the inner surface of the pipe; $Z = \frac{68}{Re}$ – (Reynolds number used for flow using additive).

$$Y = A \cdot C^p \cdot \varepsilon^b \quad (18)$$

$$X = (28 \cdot Z)^{10} \quad (19)$$

A, p, b – constant coefficients for a certain additive.

The authors of works [33-37], based on the semi-empirical theory of turbulence by T. Karman, derived a universal equation for hydraulic flow resistance together with the use of anti-turbulence additives:

$$\frac{1}{\sqrt{\lambda}} = 0{,}88 \cdot ln \ln\left[\frac{k_1(C)Re\sqrt{\lambda}}{1 + 0{,}35k_2(C) \cdot \varepsilon \cdot Re\sqrt{\lambda}}\right] - 3{,}745 \quad (20)$$

The values of the coefficients $k_1(C)$ and $k_2(C)$ are determined during experiments with additives. It is allowed to take $k_2(C) = 0.32$.

In [38-41], a model based on the power formula of A.D. Altshul was proposed:

$$\lambda_f = \left[0{,}11 \cdot \left(\frac{68}{Re} + \varepsilon\right)^{0{,}25}\right] \cdot (1 + C)^{-0{,}25} \quad (21)$$

where $\varepsilon = \frac{k}{D}$ – roughness of the inner wall of the pipe surface; D - pipeline diameter, m; Re – Reynolds number for liquid flow with anti-turbulence additives; C – concentration of antihypertensive drugs

In [42-43], the theory of T. Karman was also taken as a basis and the following equation was obtained for finding the value of the coefficient of hydraulic resistance in a flow using additives:

$$\frac{1}{\sqrt{\lambda}} = 0{,}88 \cdot ln \ln[\mathrm{A} \cdot Re \cdot \sqrt{\lambda}] - 3{,}745 \quad (22)$$

where A is a coefficient that takes into account the interaction of turbulent flow with the pipe wall, equal to A=A0=28 in the absence of additive.

One of the well-known models describing the coefficient of hydraulic resistance is the Colebrook-White model based on pipe roughness:

$$\frac{1}{\sqrt{\lambda}} = -2 \cdot log \log\left(\frac{k}{3{,}7 \cdot D} + \frac{2{,}51}{Re \cdot \sqrt{\lambda}}\right) \quad (23)$$

where k – pipe roughness.

2.3. Experimental apparatus and procedure

When developing methods for studying high-viscosity oils and choosing instruments for their implementation, it is necessary to take into account the features of the multicomponent systems under consideration. Firstly, when they flow over smooth surfaces, the effect of wall sliding occurs due to a change in their properties near the solid surface. Secondly, the presence of thixotropic properties complicates their experimental studies, since it is necessary to know and take into account the background of sample processing and the fact that the orientational thixotropic effect affects the rheological characteristics.

The essence of this effect is that, depending on the velocity field, one or another dynamically equilibrium state of the structure is created. The mutual orientation of particles ensures the predominance of a certain type of contact and interaction between them, which leads to a significant change in the properties of the original system. For experimental studies, oil from the North Komsomolskoye field was used.

Experimental studies were carried out using a rotational rheometer "Rheotest RN 4.1", widely used in the oil industry.

The general view of the rotational rheometer "Rheotest RN 4.1" is shown in Figure 1.

Figure 1. The general view of the rotational rheometer "Rheotest RN 4.1".

The main technical characteristics of the rotary viscometer "Rheotest RN 4.1" are given in Table 2.

Table 2: *The main technical characteristics of the rotary viscometer "Rheotest RN 4.1"*

Characteristics	Value
Dynamic viscosity measurement range, mPa·s	from 1 to 3.0·109
Limits of permissible relative error of the viscometer, %	±3
Number of measuring pairs, pcs.	17
Shear stress range, Pa	from 1.3 to 3.5·105
Range of shear rate gradients, s-1	from 0.04 to 20000
Temperature reading range, ℃	from -60 to +200
Smallest sample volume of the tested oil, ml	from 5 to 75 (depending on the measuring pair)

For experimental studies, oil from the Severo-Komsomolskoye oil field was used. The physical and chemical properties of oil are presented in Table 3.

Table 3: *The physical and chemical properties of oil*

Characteristics	Oil (20°C)
Density, kg/m3	945,5
Viscosity at 20°C, mm2/s	1216,2
Resin content, %	14,12
Paraffin content, %	0,62
Asphaltene content, %	1,02

At the beginning of the experiment, the oil sample is heated to the required temperature in a heating cabinet and then placed in a special cuvette of the device. After temperature control of the oil and parts of the device, the rotor is started, which begins to rotate with increasing angular velocity.

The friction force between the moving rotor and stationary oil causes the rotation of the rotor to accelerate or decelerate, which is monitored by the device's sensors. This change in rotation speed allows the dynamic viscosity of the sample to be determined.

It is important to note that measurements are carried out under strictly controlled conditions of temperature and pressure, as these parameters can significantly affect the results.

III. Results

During the experiment, graphs and values of shear stress and dynamic viscosity versus shear rate were obtained.

In Fig. 2-6 shows a graph of dynamic viscosity versus shear rate for pure oil from the North Komsomolskoye field.

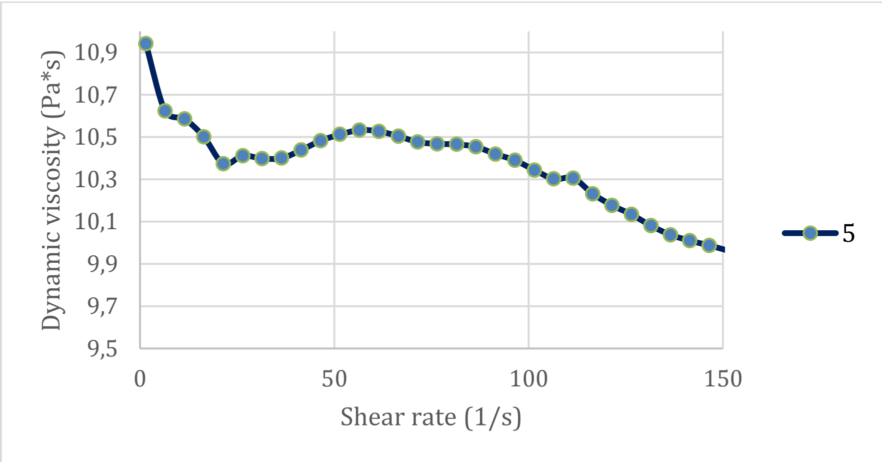

Figure 2: *Dynamic viscosity versus shear rate*

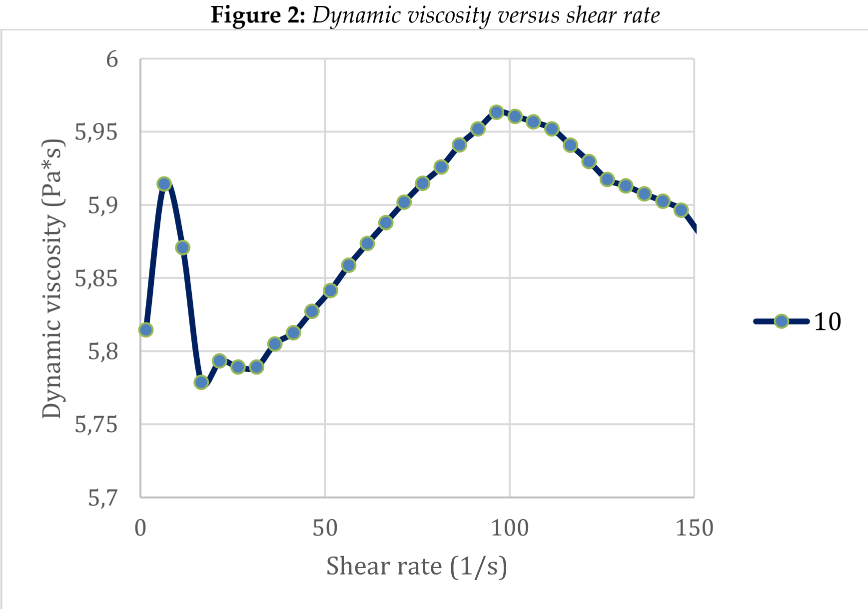

Figure 3: *Dynamic viscosity versus shear rate*

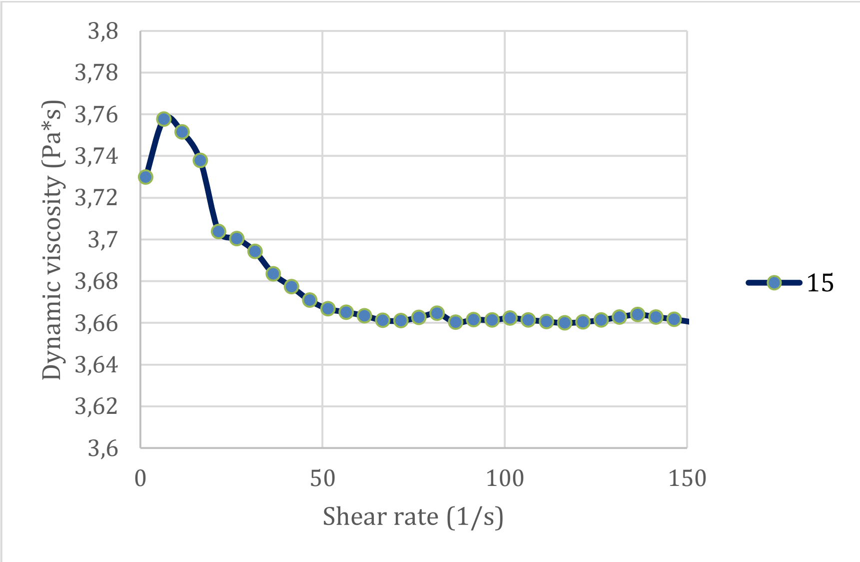

Figure 4: *Dynamic viscosity versus shear rate*

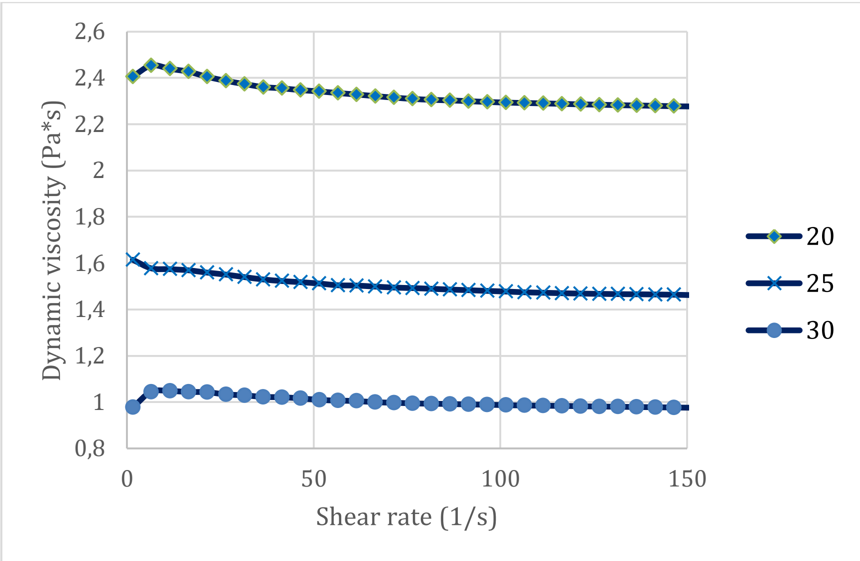

Figure 5: *Dynamic viscosity versus shear rate*

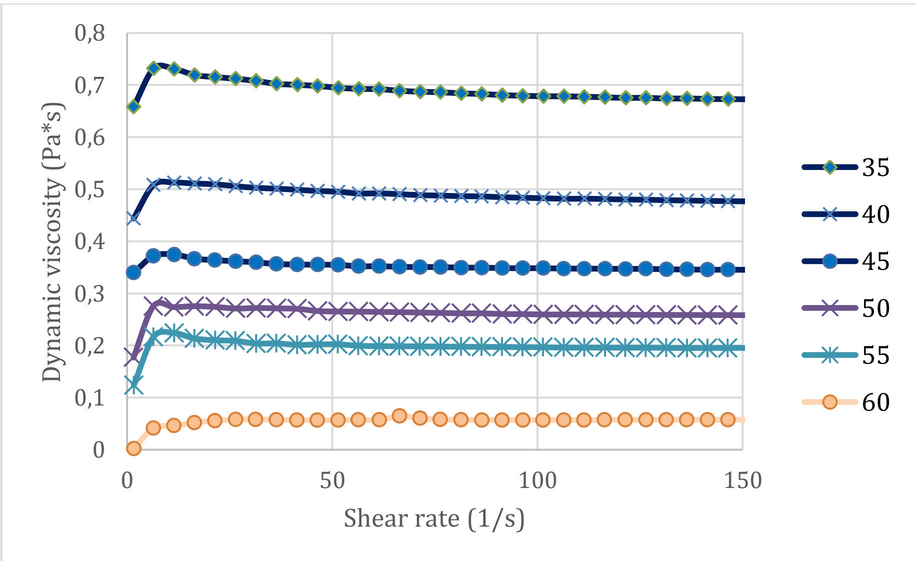

Figure 6: *Dynamic viscosity versus shear rate*

The graph shows that the oil begins to exhibit Newtonian properties in the temperature range from 40 to 45 °C (change in English version). The static shear stress at a temperature of 10 °C is 3.15 Pa (Remove).

The experimental results were processed using the least squares method. The resulting curves can be described by the nonlinear Bulkley-Herschel equation:

$$\tau = \tau_0 + k' \cdot \gamma^n \tag{24}$$

where τ_0 is the initial shear stress, k' is a coefficient depending on the consistency (the higher the viscosity, the greater k'), n is the index (depending on the shear rate).

Graphs describing the movement of liquid when adding an anti-turbulence additive at different temperatures are presented in Figure 7-10.

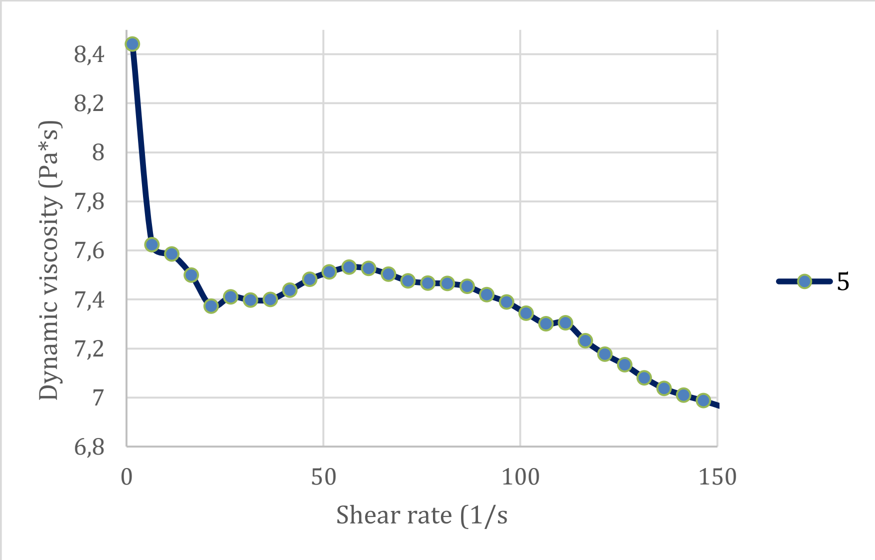

Figure 7: *Dynamic viscosity versus shear rate*

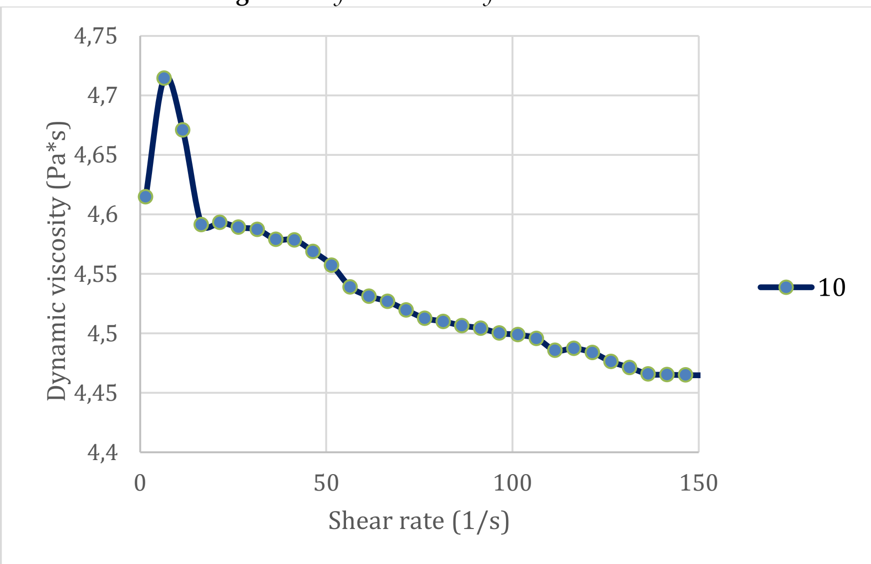

Figure 8: *Dynamic viscosity versus shear rate*

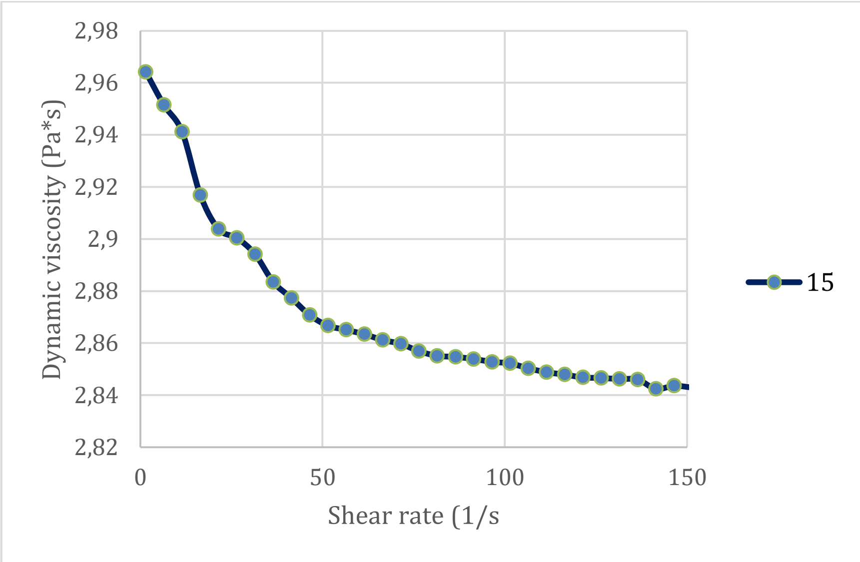

Figure 9: *Dynamic viscosity versus shear rate*

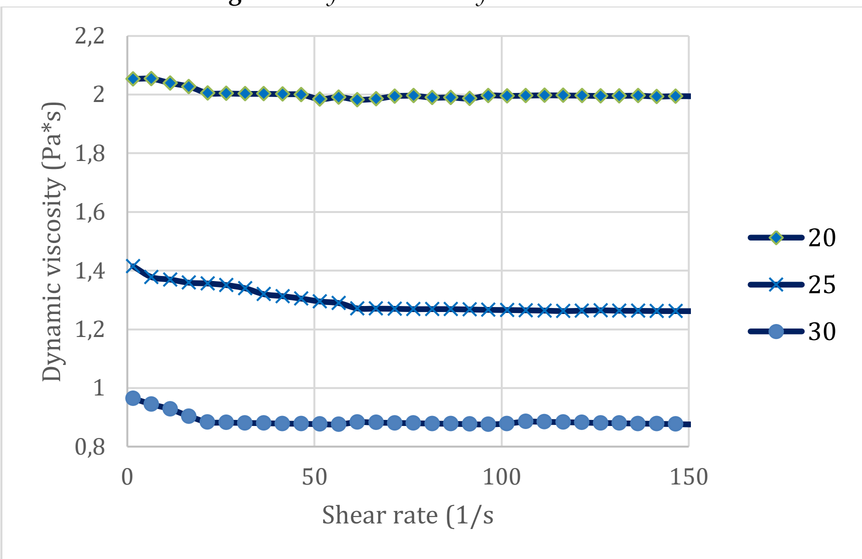

Figure 10: *Dynamic viscosity versus shear rate*

When transporting oil with an anti-turbulence additive, it is important to take into account the value of coefficient A1(0), which when transporting pure oil is a constant value, but when adding an additive changes its values and affects the value of the hydraulic resistance coefficient.

The results of determining the value of $A1(C)$ in modes using PTP are shown in Figure 12.

During the experiment, graphs and values of shear stress and dynamic viscosity from shear rate were obtained.

Figure 11 shows graph of the dependence of shear stress on shear rate.

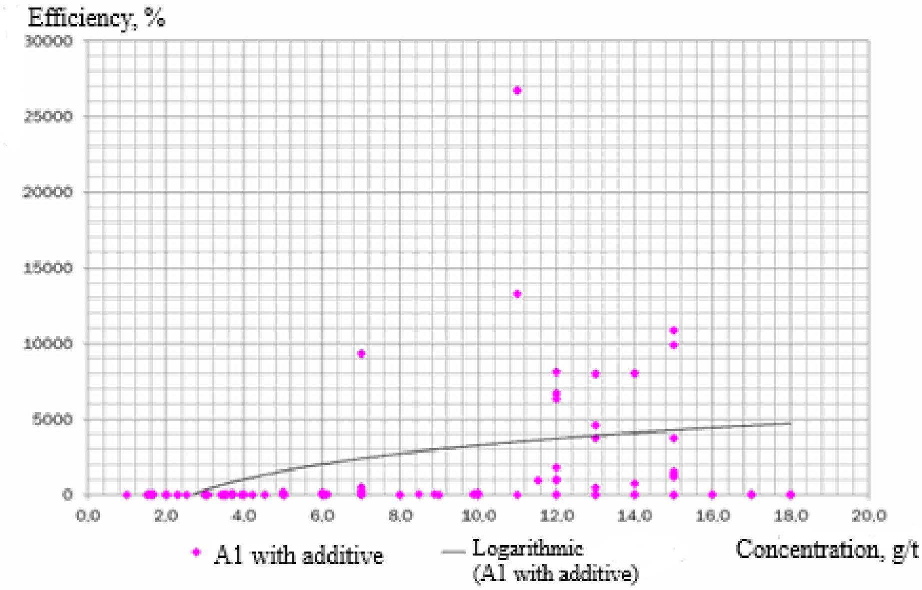

Figure 11: *Coefficient A1(C) in modes using PTP*

From Figure 11 it is clear that in modes with PTP the value of $A1$(C) varies in a wide range from 1 to several 1000. Moreover, in contrast to the literature data from Figure 3.2 it is clear that the construction of any analytical dependence of the value of $A1$(C) on concentration problematic. This indicates that the value of $A1$ is influenced not only by the concentration value, but also by a number of other factors.

To increase the accuracy of the calculation, the value of $A1$ was in the form $A1 = f\ (C,\ Re,\ \tau w)$. Based on the optimization results, a predictive calculation formula was constructed: $A1 = f\ (C,\ Re,\ \tau w)$, which gives the smallest error in determining the efficiency value ψQ. The results of comparison of actual efficiency values ψQ and calculated using the formula are presented:

$$\frac{1}{\sqrt{\lambda_f}} = 0{,}782 \cdot \ln\left(\left(1 + A_1(C, Re, \tau_w)\right) \cdot W_f\right) \tag{25}$$

From Figure 4 it can be seen that when applying the resulting formula, the convergence of the calculated data to the average efficiency values is quite good, however, some values related to high efficiencies above 60%, or low values obtained at high concentrations, differ from the calculated ones.

Based on the results of the analysis of actual and calculated values of efficiency ψQ when using the model under study, it was established that the average error is 10%.

The efficiency of PTP increases with increasing concentration of PTP in the pumped liquid; for the practical use of PTP on a specific pipeline, a curve of efficiency versus concentration ψ(C) is constructed, which is called the PTP efficiency curve. An example of this curve is shown in Figure 12.

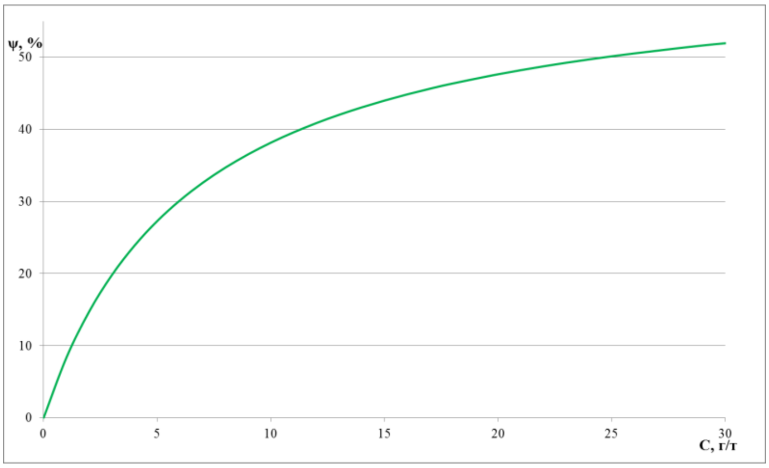

Figure 12: *DTP effectiveness curve*

The dependence of the effectiveness on the concentration of antipsychotic drugs, which quite accurately describes the behavior of antipsychotic drugs, can be presented in analytical form:

$$\frac{C}{\psi} = a + b \cdot C \quad (26)$$

Coefficients a, b are determined empirically, for example, as a result of pilot testing of PTP on a pipeline.

Based on the results of the research, a combined Q-H characteristic of pumping equipment and a section of the main pipeline with and without PTP was obtained, presented in Figure 13.

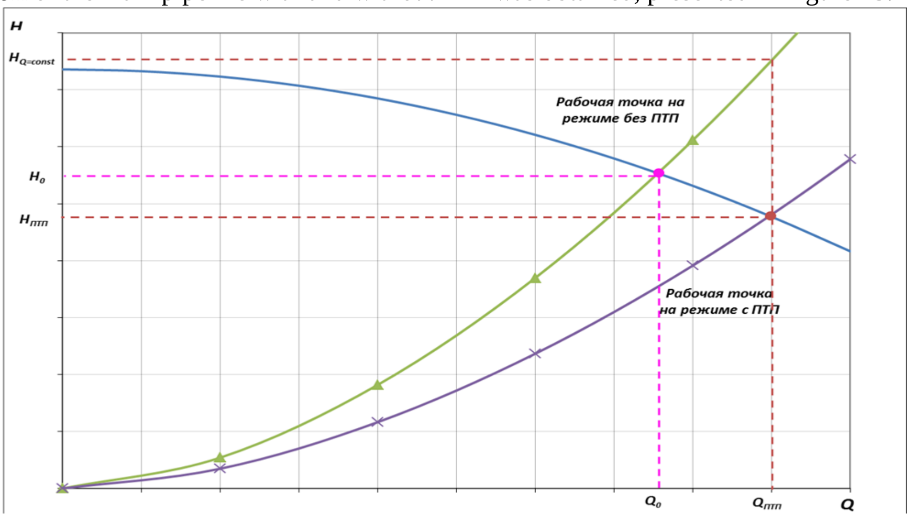

Figure 13: *Combined Q-H characteristics of pumping equipment and a section of the main pipeline with and without PTP*

In addition to the concentration of PRP, its effectiveness is influenced by a number of other factors: characteristics of the pipeline (pipeline length, its diameter, pipe wall roughness), properties of the pumped liquid (temperature, asphaltene content, solubility of PRP in the pumped liquid), flow regime (Reynolds number, shear stress on the wall of the pipeline), etc. [2].

Determination of hydraulic resistance based on the Colebrook-White equation for rough pipes:

$$\frac{1}{\sqrt{\lambda}} = 2 \cdot \log\left(\frac{Re \cdot \sqrt{\lambda}}{2{,}51} + N\right) \quad (27)$$

On the measuring line of the stand with diameter d1 and Reynolds number Re1, the value of $\frac{Re \cdot \sqrt{\lambda}}{2{,}51} + N$ is determined.

Next, the equation is solved for λ_1 for a pipeline with diameter d2:

$$\frac{1}{\sqrt{\lambda_2}} = 2 \cdot log \log\left(\frac{Re_1 \cdot \sqrt{\lambda_1}}{2{,}51} + N_1\right) \cdot \frac{d_2}{d_1}) \quad (28)$$

The Reynolds number corresponding to the found value of λ_2 is determined:

$$Re_2 = Re_1 \sqrt{\frac{\lambda_1}{\lambda_2} \cdot \frac{d_2}{d_1}} \qquad (29)$$

This method, based on experimental studies on an installation with a Re1 number, makes it possible to predict the effectiveness of the ATA for a pipeline with a diameter of d2 and the Re2 number, which depends on the ratio of diameters, the coefficient of hydraulic resistance and the Re1 number.

Table 4: *Calculation results using the Colebrook-White model*

D, mm	Consumption, m3/h	Temperature, oC	Negative roughness	Deviation of hydraulic resistance,%
50	10	20	366,8	9,2
	20			2,5
	30			-2,5
	50			-1,9

3.2. Calculation of the hydraulic resistance coefficient based on the model with the Deborah number (14):

$$\lambda\lambda_P = \frac{\lambda_0}{(1 + De^2)^m}$$

Table 5: *Results of calculations using the model with the Deborah number*

D, mm	Consumption, m3/h	Temperature, oC	α_0	α_1	De	Deviation of hydraulic resistance,%
50	10	20	121,5	-0,5134	1,9	1,6
	20		121,5	-0,5134	1,2	-1,5
	30		121,5	-0,5134	0,9	1,5
	50		121,5	-0,5134	0,7	-0,9

3.3. Calculation of the hydraulic resistance coefficient based on a model that takes into account mixture formation (19):

$$\frac{1}{\sqrt{\lambda}} = 0,88 \cdot ln \ln\left[\frac{k_1(C)Re\sqrt{\lambda}}{1 + 0,35k_2(C) \cdot \varepsilon \cdot Re\sqrt{\lambda}}\right] - 3,745$$

Results of calculation presented in Table 6.

Table 6: *Calculation results using a model that takes into account mixture formation*

D, mm	Consumption, m3/h	Temperature, oC	ε	k_1	k_2	Deviation of hydraulic resistance,%
50	10	20	0,00184	56	0,31	6,1
	20		0,00184	56	0,31	3,1
	30		0,00184	56	0,31	-2,9
	50		0,00184	56	0,31	-2,1

3.4. Calculation of the hydraulic resistance coefficient based on the T. Karman model using the transcendental equation (21):

$$\frac{1}{\sqrt{\lambda}} = 0,88 \cdot ln \ln\left[\mathrm{A} \cdot Re \cdot \sqrt{\lambda}\right] - 3,745$$

Results of calculation presented in table 7.

Table 7: *Results of calculations using the T. Karman model*

D, mm	Consumption, m3/h	Temperature, oC	A	Deviation of hydraulic resistance,%
50	10	20	41,2	9,9
	20		41,2	10,1
	30		41,2	-5,4
	50		41,2	-7,2

3.5. Calculation of the coefficient of hydraulic resistance based on the model of the universal law of resistance and Altschul's logarithmic formula:

$$\frac{1}{\sqrt{\lambda_f}} = 0{,}782 \cdot ln \ln\left[A_1 \cdot W_f\right] \tag{30}$$

where λ_f – coefficient of hydraulic resistance using ATA; $A_1(C)$ - coefficient depending on the concentration of the additive.

$$W_f = \frac{Re_f}{Re_f \cdot \frac{0{,}1 \cdot k_e}{D} + 7} \tag{31}$$

where k_e – roughness, Re_f – Reynolds number with ATA.

Table 8: *Results of calculations using the model based on the universal law of resistance and Altschul's logarithmic formula*

D, mm	Consumption, m3/h	Temperature, oC	A_1	W_f	Deviation of hydraulic resistance,%
50	10	20	1,1	406,8	6,1
	20		1,1	798,2	3,2
	30		1,1	1410,2	-2,5
	50		1,1	1850,2	-2,3

Models based on the universal law of resistance and the Altschul logarithmic formula, taking into account the Deborah number, and a model for calculating efficiency through the value of Re on the installation and the real pipeline turned out to be more accurate.

IV. Conclusions

As a result of the research, the following results were obtained:

1. Oil from the North Komsomolskoye field corresponds to the Bulkley-Herschel model and exhibits non-Newtonian properties in the temperature range from 10 to 20 degrees

2. A comparison of models of the hydraulic resistance coefficient showed that for a given type of oil the universal law of resistance and the Altschul logarithmic formula, taking into account the Deborah number and a model for calculating efficiency through the value of Re on the installation and the real pipeline.

STUDY OF VULNERABILITY AND PROTECTION OF BUILDINGS AND STRUCTURES ON STRUCTURALLY UNSTABLE CLAY SOILS

Fakhraddin Gabibov
•
Scientific Research Institute of Construction and Architecture, AZERBAİJAN
farchad@yandex.ru

Abstract

The study provides a clear definition of the vulnerability of buildings and structures designed and operated on structurally unstable clay soils. The condition of critical external negative impact on structurally unstable clay soil was considered as a random variable. Distribution functions were given for various degrees of damage or destruction of objects on structurally unstable clay soils. The methodology for study and construction of engineering protection schemes for objects designed and operated on structurally unstable clay soils was presented. An example of the energy balance of the object engineering protection with optimal loading of the building was given schematically. A scheme for protection of an object on structurally unstable clay soils with their optimal loading and a scheme for protection of an object on subsiding soils using a screen and drainage were also provided. A formula was given for determining the degree of implementation of the objectives of protecting objects on structurally unstable clay soils

Keywords: vulnerability, structurally unstable soil, building, structure, engineering protection, scheme

I. Introduction

The threat of damage to structures due to uneven deformations of structurally unstable clay soils (subsiding, swelling, populated and water-saturated) depends on the relative position of the source of soil moisture or drying and the action of various loads (primarily the weight of the structure itself) acting on the structurally unstable soil.

A threat of negative impact on structurally unstable soil causes occurrence of damage if this negative impact (a sharp change in the moisture content of structurally unstable clay soils) leads to critical uneven deformations of buildings and structures. Then the structures are damaged or, in extreme cases, go into an emergency state (complete destruction), leading to significant discomfort (material and psychological) for the owners and people operating the facilities. The possibility of damage and destruction of buildings and structures due to the impact of adverse factors on structurally unstable clay soil depends on the vulnerability of the building (structure) - structurally unstable (clay) soil system. The issues related to the study of the vulnerability of technical systems and territories to various adverse impacts are discussed in the monographs by V.A. Akimov, N.N. Radayev, V.D. Novikov, V.V. Lesnykh [1, 2], V.V. Bolotin [3], A.A. Rogozin [4], V.A. Vladimirov, Yu.L. Vorobyev, N.A. Makhutov and et al. [5], V.T. Alymov and N.P. Tarasova [6], N.N. Chura [7] et al.Vulnerability, by definition, depends both on the properties of the object itself and its ability to withstand adverse impacts, as well as on the intensity of these impacts [4].

II. Theoretical definition of vulnerability of engineering structures on structurally unstable clay soils

Let $\Delta_{cr.}$ critical action (moisture, leaching, evaporation, transpiration, and the pressure of water extrusion from the soil) at which damage or failure of a building or structure doesn't occur. Critical action characterizes the geotechnical stability of a building or structure against external adverse impacts. Geotechnical stability is the property of a construction object (building, structure) to maintain its geotechnical parameters within construction norms and rules and perform its functions during and after external adverse impacts on structurally unstable soil. The property of a building or structure opposite to geotechnical stability is geotechnical vulnerability (it can be called conditional geotechnical vulnerability). The characteristic of conditional geotechnical vulnerability of a geotechnical object coincides with the characteristic of the geotechnical ultimate stability of the object (building or structure). This critical external action (or actions) is the threshold beyond which damage occurs, leading to a geotechnical emergency situation.

$$\Delta'_{cr} \equiv \Delta_{cr}, \tag{1}$$

In geotechnical calculations and related engineering assessments of the consequences of hazardous influences on structurally unstable clay soils due to the effects of individual unstable factors (duration of exposure, quantity of negative agents affecting the unstable soil, influence of adjacent soils), the critical action can be treated as a random variable *Jcr.* The complete probabilistic characteristic of conditional geotechnical vulnerability of buildings and structures is the distribution function of critical action:

$$F_{cr}(\Delta_{cr}) = P(J_{cr} < \Delta_{cr}), \tag{2}$$

Distribution function $F_{cr}(\Delta_{cr})$ for geotechnical objects of a specific type can be considered as the physical laws governing the damage or failure of buildings or structures under consideration of the detrimental effect.

The random variable of critical action on known types of structurally unstable soils, interacting with typical buildings or structures, is typically distributed according to the normal law:

$$J_{cr} \in N(\mu_{cr}, \sigma^2_{cr}), \tag{3}$$

where μ_{cr} is the mean of the critical action on structurally unstable clay soils, and $\sigma^2_{\Delta_{cr}}$ - variance of the mean expectation Δ_{cr}.

Accordingly, the complete probabilistic stability of geotechnical objects under critical external actions is characterized by the function:

$$R_{cr}(\Delta_{cr}) = P(J_{cr} \geq \Delta_{cr}) = 1 \cdot F_{cr}(\Delta_{cr}) \tag{4}$$

representing the dependence of the probability of geotechnical objects stability on the considered structurally unstable clay soils on the level of adverse external impact.
Different distribution functions are distinguished

$$F_{cr}(\Delta_{cr} \geq |d) = P(J_{cr.d} < \Delta_{cr}) \tag{5}$$

for different degrees *d* of damage or destruction of objects on structurally unstable clay soils, or for degrees of damage or destruction not less than a specified D:

$$F_{cr}(\Delta_{cr}|D) = \sum_{d=1}^{D} F_{cr}(\Delta_{cr}|d). \tag{6}$$

These functions for each object situated on structurally unstable clay soils can be established on the basis of existing experience gained from analyzing the consequences of past damages and failures of buildings and structures on structurally unstable clay soils. This can also be derived from assessments of the resilience of buildings and structures under uneven deformations of structurally unstable clay soils. Critical external factors for specific geotechnical objects can be evaluated through the following methods:

- field-experimental methods: using data on the degree of damage and destruction of buildings or structures of similar construction on corresponding types of structurally unstable clay soils due to previous adverse external factors;
- computational-experimental methods: based on the results of studies on the response of buildings or structures to trial external impacts on structurally unstable clay soils with which these buildings or structures come into contact;
- computational-modeling methods: employing theoretical models and computer programs considering the structural features of buildings or structures to resist damages and emergencies both in normal conditions and with engineering protection against various adverse external impacts on structurally unstable clay soils.

$F_{cr}\left(\Delta_{cr}|d\right)$ for a fixed critical adverse external impact on structurally unstable clay soils, Δ_{cr} can be called "physical vulnerability" of buildings or structures interacting with structurally unstable soils referring to the proportion

$$\alpha_d\left(\Delta_{cr}\right) = N_d\left(\Delta_{cr}\right)/N \quad (7)$$

of damaged (destroyed) buildings or structures in the case of a specified intensity of Δ_{cr} . B (7) $N_d\left(\Delta_{cr}\right)$ of external negative impact *d*, representing the number of buildings (structures) that incurred damage (destruction) from the total number *N* of buildings (structures) interacting with structurally unstable clay soils in the area affected by the specific intensity of external negative impact Δ_{cr} . As is evident, mathematically, they coincide:

$$\alpha_d\left(\Delta_{cr}\right) \equiv F_{cr}\left(\Delta_{cr}|d\right). \quad (8)$$

III. Methodology for the study of the schemes for engineering protection and objects on structurally unstable clay soils

The stability of the considered geotechnical objects is established on the basis of everyday experience and experimental construction and operation of buildings or structures on structurally unstable clay soils. This stability is then codified in building codes, regulations, and guidelines at a level where the prevented damage from failures and accidents still outweighs the additional costs of engineering protective measures enhancing the stability of these objects constructed and operated on structurally unstable clay soils.

According to the modern standards, engineering protective measures against external negative impacts and the uneven deformations caused by them increase the cost of buildings and structures by 20-40%. Without these protective measures, repair costs for buildings and structures, depending on the type of unstable soils, range from at least 20-50% up to the complete demolition of the emergency structure, resulting in 100% loss of the object, plus costs for demolition and site remediation of the affected area.

The damage (destruction) possibility to considered geotechnical structures and the occurrence of emergency situations significantly depends on the protection of buildings or structures on structurally unstable clay soils, ensured through the implementation of preliminary protective engineering measures included in the construction project of buildings and structures on territories occupied by structurally unstable clay soils.

Methodological principles for engineering protection of buildings and structures operated on structurally unstable clay soils are proposed against various hazardous negative externalities on the basis of alteration of energy potentials.

The following components are identified for solving the problem of engineering protection of objects designed and operated on structurally unstable clay soils: the source of negative externality (Δ), the source of constant load (q) from the building or structure, the source of probabilistic short-term external (seismic) impact (S), the receiver (structurally unstable soil) of external impact (T), and the engineering protection which shields or reduces the intensity level of negative externality on structurally unstable clay soils to permissible values for safe construction and operation of objects (Z).

Let's consider from the total flow of negative energy E directed towards the receiver T and entering the engineering protection Z (Fig. 1), part E is reflected (shielded), part E_2 is absorbed by the receiver (soil) T, and part E_3 is dissipated into zones outside the receiver T. Thus, Z can be characterized by the following energetic coefficients:

– reflection coefficient $\xi = E_1 / E$,
– absorption coefficient $\beta = E_2 / E$,
– dissipation coefficient $\rho = E_3 / E$.

The overall equilibrium state of geotechnical object is represented as follows:

$$\xi + p + s = 1. \tag{9}$$

Sum

$$\beta + \rho = 1 - \xi - h, \tag{10}$$

where

$$h = E_h / E, \tag{11}$$

characterizing the unreflected energy flow E_h passed into the engineering protection Z.

If $\beta = 1$, then Z reflects all the energy of negative externality on the structurally unstable clay soil.

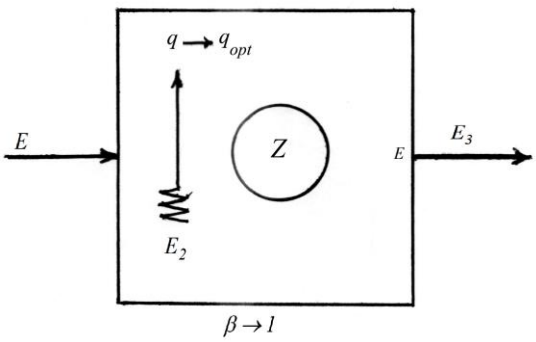

Figure 1: *Example of the energy balance of engineering protection for an object on structurally unstable clay soil (q_{opt} - optimal load)*

If $\rho = 1$, then Z reflects all negative energy from external impacts on the object associated with structurally unstable clay soil.

In practice, protective measures are often used in a combined form, for example $\xi + \rho = 1$. This means employing protective anti-filtration screens and draining water away from the protected area beyond its boundaries using specialized drainage systems.

The study [8] represents the examples of absorbing negative externalitys (soaking) on structurally unstable subsidence and swelling clay soils, with a protective measure involving maximizing water absorption by the soil. In these examples, techniques for optimizing the load from buildings or structures on the foundation soil were employed, specifically $q \rightarrow q_{opt}$. .

In the first example, the base area of the building foundation was maximally expanded (replacing strip foundation with a raft foundation). This approach achieved a specific pressure on the subsiding soil that was lower than the initial settling pressure. In the second case, the width of the strip foundation of a building on swelling clay soil was reduced to ensure that the specific pressure from the foundation on the soil base was less than the active pressure due to swelling of the clay soil [9]. The energy protection balance scheme for engineering protection of objects on structurally unstable soils during $\beta \rightarrow 1$ is shown in Fig. 1.

For the aforementioned examples, the protective engineering measure Z ensured achieving optimal loading of structurally unstable clay soils (subsiding and swelling) by buildings constructed on them, denoted as q_{opt} . This approach made structurally unstable soils fully transparent to negative externalities (soaking).

Fig. 2 illustrates the transparency scheme of structurally unstable clay soils to external negative moisture (W) under optimal loading conditions of structurally unstable soils (T).

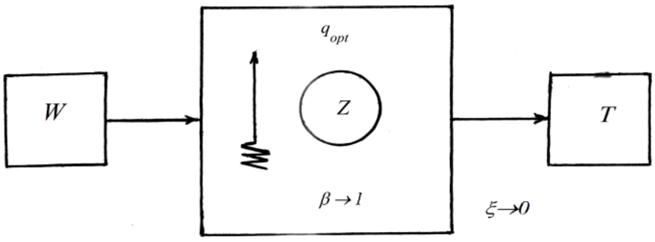

Figure 2: *Scheme of protection for geotechnical object on structurally unstable clay soils at their optimal loading*

Consider the case, when the building is located on subsidiary soil of a type II along the subsidence. In its natural state, the building retains its stability due to the structural strength of subsidiary soil. The building will go into a state of emergency under a negative externality (uneven soaking) due to uneven subsidence of the substrate. For the purpose of preventing an accident, a comprehensive protective film screen and drainage are provided.

Fig. 3 shows the scheme of reflection (screen) and removal (drainage) of negative externality (soaking) on subsidiary soil, loaded with the weight of the building, exceeding its structural strength in the moistened state.

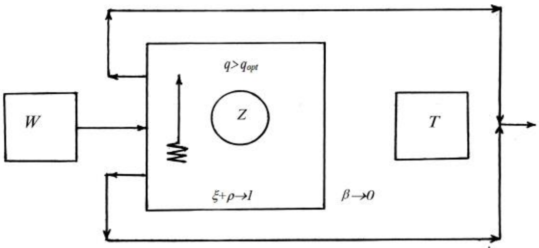

Figure 3: *Scheme of protection of an object on subsidiary soil in the case of using reflective anti-filtration screen and discharge drainage*

Realization degree of the objectives of protection of buildings or facilities (objects), erected and operated on structurally unstable clay soils can be expressed by:

$$K_s = \frac{M_z}{M_w} \tag{12}$$

where *K* is the protection coefficient of the object on structurally unstable clay soils; M_z – the cost of protective engineering measures; M_w – the cost of repairing a geotechnical object damaged or affected by the negative externality *W* (uneven soaking).

If $K_s \leq 0{,}3$ this is considered acceptable for the design and practical implementation of protective engineering measures. If $0.31 \geq K_s \geq 0.50$ this is considered a necessary condition for the design and practical implementation of protective engineering measures when there is no choice of construction site for critical buildings and structures. If $K_s > 0.50$, this is considered an unacceptable condition for the design and implementation of protective measures for geotechnical objects on structurally unstable clay soils.

IV. Conclusion

A threat of negative impact on structurally unstable soil causes occurrence of damage if this negative impact leads to critical uneven deformations of buildings and structures.

In geotechnical calculations and related engineering assessments of the consequences of hazardous influences on structurally unstable clay soils due to the effects of individual unstable factors, the critical action can be treated as a random variable.

The random variable of critical action on known types of structurally unstable soils, interacting with typical buildings or structures, is typically distributed according to the normal law. Critical external factors for specific geotechnical objects can be evaluated through the following methods: field-experimental methods; computational-experimental methods; computational-modeling methods.

Methodological principles for engineering protection of buildings and structures operated on structurally unstable clay soils are proposed against various hazardous negative externalities on the basis of alteration of energy potentials. The schemes are given of protection for geotechnical object on structurally unstable clay soils at their optimal loading and of an object on subsidiary soil in the case of using reflective anti-filtration screen and discharge drainage.

It is proposed to define realization degree of the objectives of protection of buildings or facilities (objects), erected and operated on structurally unstable clay soils through the object's protection factor.

Abstract

The issues of reliability and efficiency of operation of field and main oil and gas pipelines and control of energy characteristics during their operation are of no small importance. The efficiency of pipelines depends on the technical condition of facilities and equipment and the rationality of their use. The practice of operating pipelines shows that emergency and abnormal cases occur in them. Significant irregular pressure and flow pulsations are observed in pipelines. Waves of high and low shock pressure often occur and propagate along the pipeline.
Along with density, additional pressure in the system from hydrodynamic impacts also arises from the elasticity of the pumped liquid and the pipeline itself. This pressure is determined by the elastic compression of the transported system and the elastic expansion of the pipeline as the pressure in it increases. The pipeline through which the multiphase flow is pumped, and its structures and other components must withstand dynamic loads.
The work analyzes various modes of water impact. The volume of oil caused by its compression during hydraulic impact was calculated. The results of calculating the increase of an oil pipeline volume due to a dynamic impact are presented.

Keywords: Water impact, dynamic load, energy feature, elasticity, multiphase flow, flow structure.

I. Introduction

As it is known, any change in the parameters of pumping oils (petroleum products) through a pipeline can be called a hydraulic impact. Such a change can occur slowly or quickly; the cause of the shock can be the slow or fast closing or opening of shut-off valves, stopping or starting a pump, the destruction of a pressure pipeline with the release of the pumped product onto the relief, as well as various dynamic loads that arise during the operation of multiphase pipelines [1 ,2,3,4].

The pressure value during water impact according to Zhukovsky can be calculated using the following formula:

$$P = c \cdot \Delta \upsilon \cdot \rho \quad (1)$$

Where c is the speed of sound propagation in a fluid at rest;
$\Delta\upsilon$– reduction of flow velocity in the pipeline;
ρ– density of pumped oil.

The practice of operating field pipelines shows that significant irregular pulsations of pressure and flow are observed in pipelines transporting multiphase mixtures. The working environments of the oil field are characterized by the presence of liquid and gas phases, which coexist in almost all oil field pipelines [6-9].

Analysis of the parameters of water impact pressure distribution along the length of the pipeline allows to choose tactics and methods for protecting the system from impact. It was found that transient conditions during the transportation of gas-saturated oils through oil pipelines are a consequence of the same reasons as during the transportation of degassed oils. Waves of increased and decreased impact pressure, propagating along the pipeline also occur [2,10]. In this case, the wave of increased pressure has the greatest magnitude and, propagating towards the previous operating station, is superimposed on the existing pressure in the oil pipeline, summing up with it. A wave of low pressure, which moves at the speed of impact wave propagation in the liquid towards the subsequent pumping station, can cause the release of gas from gas-saturated oil and lead to the formation of gas accumulations in the oil pipeline and cavitation of pumps. As for transient regimes when pumping gas-saturated oils, they do not introduce significant changes and can be assessed using existing methods for calculating transient regimes in degassed oils. In this case, the relative change in the pressure increase in the disturbed gas-saturated flows will be determined by the relative change in the bulk elasticity modulus of gas-saturated oil.

In [6,9], taking into account changes in the structural forms of flow of multiphase systems based on an estimate of the critical flow velocity, the issues of distribution of dynamic loads were considered and it was found that when the gas phase dominates in the system, with increasing ratio of the density of liquid and gas, the dynamic load grows significantly.

II. Methods

As a rule, additional pressure during the operation of pipelines due to water impact arises from the density of the transported liquid, its elasticity and the elasticity of the pipeline itself. The practice of operating field and main pipelines shows that, due to impact pressures, the energy characteristics of pipeline systems can change significantly depending on the intensity of hydraulic pressure. Water impact pressure is determined by two factors: the elastic compression of the transported oil or petroleum product and the elastic expansion of the pipeline itself when the pressure in it changes. The change in the density of transported oil with changes in pressure can be assessed using the following relationship:

$$\rho(P) = \rho_{20}[1 + \beta_o(P - P_{atm})] \tag{2}$$

Where ρ_{20} is the density of oil at 20 ^{0}C, kg/m ^{3};
P– pressure, Pa;
P_{atm}– atmospheric pressure, Pa;
β_o– oil compressibility coefficient (β= 0.00078 MPa $^{-1}$)
The change in the volume of oil in the pipeline (ΔV_o) depends on its modulus of elasticity $E_o = 1/\beta_o$ and the level of hydraulic pressure (P):

$$\Delta V_o = P \cdot V_o / E_o \tag{3}$$

Where V_o *is* the volume of oil in the pipeline, m^3;

$$V_o = V_p = \frac{\text{ПД}^2}{4} \cdot l \tag{4}$$

D and l are the diameter and length of the oil pipeline, respectively, m
The change in pipeline volume during water impact can be calculated using the following formula [5]:

$$\Delta V_{т} = \frac{ПД^3 \cdot P \cdot l}{2E_{т} \cdot \delta} \qquad (5)$$

Here δ is the thickness of the pipeline wall;
E_p– modulus of elasticity of the pipe material ($E_p = 2{,}1 \cdot 10^{11}\ Pa$)

It should be noted that the duration of the change in liquid volume is equal to the duration of the impact phase, which is equal to the travel time of the pressure wave from the disturbance to the barrier and back

$$t = 2l/c$$

The speed of sound propagation in oil is determined by the well-known formula [3,5]:

$$c = \frac{\sqrt{E_o/\rho_o}}{\sqrt{(1 + E_o \cdot Д/(E_p \cdot \delta)}} \qquad (6)$$

Let's consider an example of calculating changes in the volume of oil and a pipeline during a hydraulic shock.

We take as initial data:

- Pipeline length l= 5000 m ;
- Pipeline diameter D = 500 mm;
- Wall thickness $\delta = 10\text{mm}$;
- Oil pipeline volume $V_p = \frac{ПД^2}{4} \cdot l = \frac{3{,}14 \cdot (0{,}5)^2}{4} \cdot 5000 = 981{,}25\ m^3$;
- Oil consumption Q_o=1500 m^3/hour= 0.4166 m^3/s ;
- Oil density $\rho_o = 860\ kg/m^3$

We can calculate the water hammer pressure for the full shock that occurs when the valves are instantly closed. The oil velocity in the pipeline was :

$$v = \frac{4Q}{ПД^2} = \frac{4 \cdot 0{,}4166}{3{,}14 \cdot (0{,}5)^2} = 2{,}12\ m/s$$

We calculate the speed of sound propagation in oil using formula (4):$C = 1074{,}2\ m/s$

Then from formula (1) the pressure from the water hammer will be:

$$P = 1074{,}2 \cdot 2{,}12 \cdot 860 = 1958481\ Pa = 1{,}96\ MPa$$

As it can be seen from the calculation of hydraulic pressure, such pressure can arise with a long pipeline length exceeding the value $l > 2 \cdot c \cdot t$; t– valve closing time.

Let's consider calculations of the volume of oil caused by its compression during a hydraulic shock. It is known that the elastic property of oil when it encounters a valve will continue until the compression wave reflected from the beginning of the oil pipeline meets a direct compression wave. The duration of the increase in pressure in the oil pipeline will be :

$$t = \frac{2l}{c} = \frac{2 \cdot 5000}{1074{,}2} = 9{,}31\ s$$

Then the compression of oil in the pipeline by additional pressure at the elastic modulus of oil $E_o = \frac{1}{\beta_o} = 1{,}3 \cdot 10^9$ Pa will be (according to formula (3)):

$$\Delta V_o = 1958481 \cdot \frac{981{,}25}{1{,}3} \cdot 10^9 = 1{,}4782\ \text{m}^3$$

At the end, we will determine the increase in the volume of the oil pipeline itself due to impact according to formula (5):

$$\Delta V_p = \frac{3{,}14 \cdot (0{,}5)^3 \cdot 1958481 \cdot 5000}{2 \cdot 2{,}1 \cdot 10^{11} \cdot 0{,}01} = 0{,}9151\ m^3$$

It is also possible to calculate changes in oil density when pressure changes as a result of impact. Using formula (2) we obtain:

$$\rho = \rho_{20}[1 + \beta_o(P - 1)] = 860[1 + 0{,}00078 \cdot 10^{-6}(1958481 - 10^5) = 861{,}29\ kg/m^3$$

Then the water impact pressure will have the following value:

$$P = 1074{,}2 \cdot 2{,}12 \cdot 861{,}29 = 1961419\ Pa$$

In this case, the effect of changes in density will be 1961419 – 1958481 = 2938 Pa

III. Results

1. Various dynamic loads arising during the operation of multiphase pipelines were analyzed.
2. In order to ensure the reliability of pipelines, in addition to single-phase movement, dynamic loads must also be taken into account for gas inclusions and multiphase flow with various structural forms of movement in field pipelines

Abstract

In the article, the analysis of the factors affecting the reduction of oil production in the hydrocarbon fields of the republic, which are in the last period of development, and the analysis of the existing problems in the exploitation of those fields are given. At the same time, referring to the scientific researches and actual oil field products, the sources of attracting investment in the production of residual oil reserves that can be extracted from the deposits, the importance of the development and application of innovative techniques and technologies, the use of the research work of scientists and specialists of scientific institutions in solving problems related to the intensification of oil production. ways and solutions of the state's problems were explained.

Keywords: deposit, oil, natural resource, production, investment, innovation, progressive methods

I. Introduction

It is known that the oil industry is the most important structural component of the country's economy, and thanks to it more than 50% of the state budget is formed, which is one of the main factors in ensuring the vital activity of the country's population.

As of 01.01.2023, 81 oil and gas fields have been discovered in the territory of the Republic of Azerbaijan. At present, hydrocarbons are produced from 58 fields, while 23 fields are not included in the development or their operation has been stopped due to objective and subjective reasons. 39 beds under development are located on land and 19 beds are located in the sea area. In 2023, the development of 28 fields (including 15 onshore and 13 offshore fields) was continued by "Azneft" PU.

Evaluating the prospects of oil production in the world, it can be said that the era of cheap and easily produced oil is over. At the same time, in Azerbaijan, as in the whole world, the share of hard-to-renew resources is increasing year by year and has exceeded 65% so far. Forecasts of the dynamics of the reserve structure do not create optimism, and by 2025, the share of hard-to-renew reserves in Azerbaijan will exceed 70%, and active reserves will be produced by 80%.

The British BP company's report published in the World Energy 2022 annual statistical overview lists oil-producing countries, and the oil reserves of our country are 7 billion barrels. Despite the fact that the republic has large hydrocarbon reserves, for more than 10 years, oil production and export of oil products have been decreasing every year. According to official information, Azerbaijan's income from the export of crude oil and oil products in 2023 decreased to slightly more than 16 billion dollars compared to 19.5 billion dollars in 2022. The statistics of the State Customs Committee show that the share of crude oil and oil products in the total volume of

Azerbaijan's exports decreased to 47.91 percent compared to 51.08 percent in 2022. This is directly related to the decrease in oil production (Fig. 1).

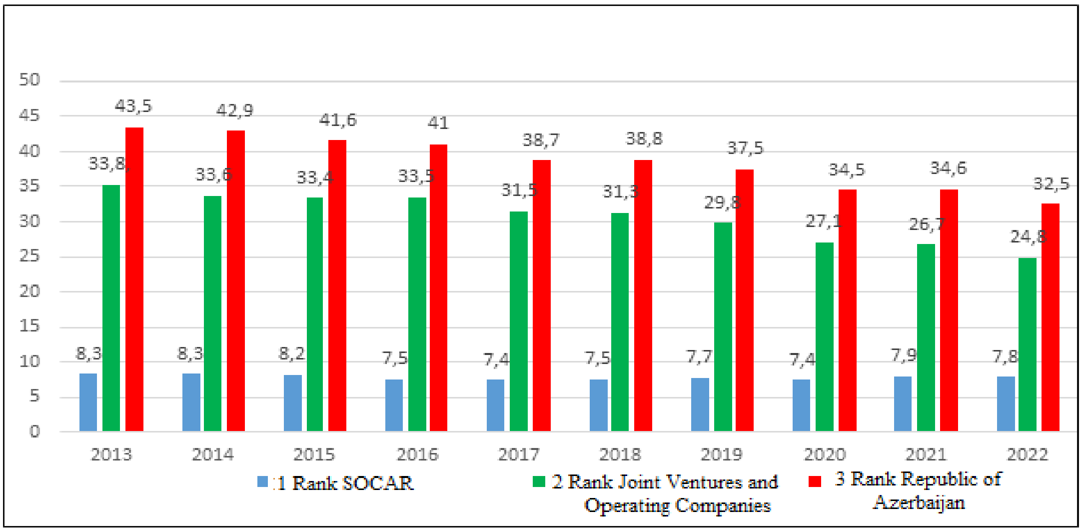

Figure 1: *Dynamics of oil production in the Republic of Azerbaijan in 2013-2022 (million tons)*

As can be seen from the picture, oil production has decreased by 11 million tons or 25.3% over the last ten years, along with the projects implemented together with foreign companies. Thus, oil production for the mentioned activity in 2013 is 43.5 million. 32.5 million tons in 2022. down to a ton.

It should be noted that along with foreign companies, Joint Ventures and Operating Companies of the republic, oil will be produced from fields located in long-term operating onshore and offshore fields. The reduction of production in these fields continues every year (Fig. 2).

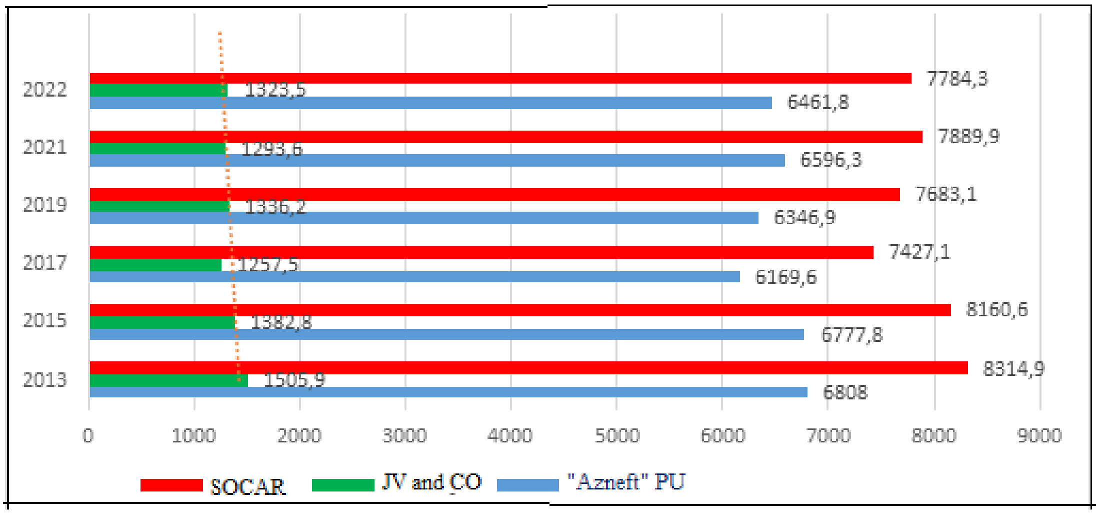

Figure 2: *Dynamics of oil production at SOCAR (2013-2022, million tons)*

According to SOCAR, oil production in the country's territories increased from 8,314.8 million tons in 2013 to 7,784.3 million tons in 2022, and the rate of decline in production in 10 years was 6.0%.

II. Methods

The problem of optimizing the development of oil fields involves a number of main problems, including the justification of the economic criterion of the efficiency of the exploitation of fields, the verification of the volume of natural resources by geological methods, the development and application of modern innovative technologies, the rationalization and application of effective methods, the acceleration of the application of scientifically based inventions and patents, etc. it is necessary to solve the issues. The issues of prevention and intensification of production decline in oil fields have been widely covered in the works and research works of many local and foreign scientists and experts.

Based on the results of our scientific research and actual oil fields, the following are the important factors that affect the reduction of production in the hydrocarbon fields located in the land and sea areas of our republic, which are in the final stage of development (the volume of reserves that can be extracted from these fields is close to 300 million tons). According to the assessment of the "De Golyer and MacNaughton" company, the total reserves of oil (proven, possible and probable) in the dry areas of the Republic of Azerbaijan are 2 billion barrels.

- As a result of over 100-150 years of working of the deposits, the percentage of wetted layers is 90-95%
- Lower formation pressure and temperature makes it difficult for oil to flow to the bottom of the well, allowing "dead" oil to remain in the formations.
- As a result of the increase in the viscosity of oil in the layers, the flow rate of oil decreases and the surface tension increases
- Failure to apply advanced methods for oil reserves that are difficult to extract;
- Formation of sand plug in wells
- The construction of well structures in oil and gas fields and the failure to take into account the geological and physical characteristics of the fields in the project materials related to the drilling of wells creates conditions for the occurrence of accidents in the processes of well drilling.
- Mistakes made in designing the development of oil and gas fields
- Non-intermittent operation of small production wells
- In the development of oil and gas fields, not investigating the issues of increasing the oil yield coefficient of the fields and not applying progressive methods in the production of oil and gas from the fields
- Non-involvement of scientists and non-specialists of scientific research and higher institutions in solving existing problems, etc.

III. Results

Determining the extent of residual oil and gas reserves in the fields based on 4D cartography technologies is one of the main aspects of solving the problems of hydrocarbon deposits. Resource assessment with geophysical methods plays a fundamental role. Thus, the volume of hydrocarbon reserves is one of the main components of the oil company's activity. Volume assessment In modern times, the importance of investments in the oil industry has increased to such an extent that they have already begun to have a political character. In this regard, it will allow the application of new advanced techniques and technologies in the stabilization of oil production in fields that are in the final stage of development. It is important to provide state support for investment in the development of the oil sector. The purpose of investment projects from this approach is to make the operation of the oil and gas extraction enterprise necessary to solve the following issues:

♦ identification of new resource sources;
♦ replacement of capital funds;

♦ reconstruction of capital funds;
♦ modernization of capital funds;
♦ commissioning of new construction facilities;
♦ purchase and installation of new advanced equipment, machinery and equipment.

The demand for oil in the industry is increasing day by day. For this reason, geophysical control in exploited oil and gas fields should be organized in such a way that it meets the requirements of the day. During the control of the deposits by geophysical methods, numerous petrophysical-geological operational issues should be studied to allow timely implementation of various measures in the wells. In addition to increasing the service life of the field, this should enable maximum hydrocarbon production from it. Analyzing the current state of development of Azerbaijan's oil and gas fields and monitoring them with well geophysical research methods, we will determine the following development directions:

* selection of optimal complexes for increasing the efficiency of control over the development of oil and gas fields with geophysical methods;

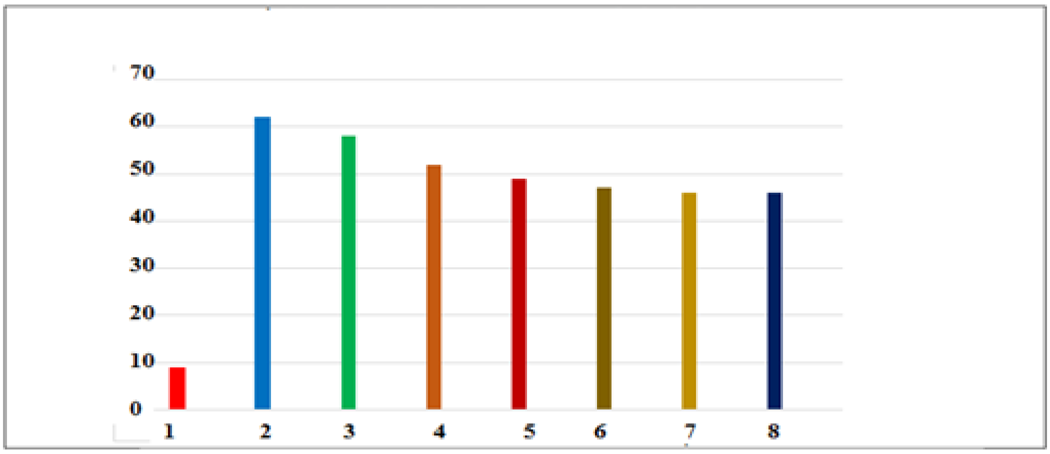
*development of more effective new interpretation methods for the assessment of the energy of oil and gas fields, the operating regimes applied to the formations that make up it, the collector properties of the formations and formation pressure;

*determining the technology and sequence of developing a satisfactory model of oil and gas field development control with QGT methods;

* selection of effective methods of influence to maximize productivity in oil and gas fields.

At present, solving the problems of the development of economic systems based on the methods of integrated assessment and management of the level of innovative development potential in the oil industry makes the development of new scientific approaches more and more urgent. In order to solve these issues, first of all, it is necessary to theoretically justify the essence and content of the structural components of the innovative potential in industries, and the methodological bases of the integral assessment of the interaction of their internal and external environmental factors. Thus, the analysis of scientific sources dedicated to the assessment and management of innovative technologies shows that there are practically very few theoretical and methodological provisions related to the development of models and methods for the integrated assessment and management of the level of innovative potential. In order to achieve the strategic goals of innovative development, the integral assessment of the development of economic systems at the micro and macro levels is a very urgent issue.

When determining the degree of efficiency of innovative activity in comparison with developed countries, it is clear that the overall level of innovative activity is only 4.3% according to the data of 2020. For comparison, let us show that the level of this indicator in Germany, Brazil, Canada, Israel and other countries is 30-35 times higher than ours (Figure 3).



1-Russiya, 2- Germany, 3 - Canada, 4 - Belgium, 5 - Switzerland, 6 - Finland, 7- Estonia, 8 – Israel

Figure 3: *The level of innovation in industrial sectors of developed countries,%*

From the analysis of the picture, it can be concluded that the following issues should be resolved in order to eliminate the low innovative activity of the republic's oil mining enterprises and the insufficient use of their innovative potential:

1. To support the involvement of small and medium businesses in oil production areas.
2. Solving issues related to classification criteria of enterprises according to the level of innovative activity.
3. To adapt the solution of problems of oil production of scientific research works.
4. Provision of concessional loans for the innovative development of enterprises.

Since the beginning of the 20th century, most US and Western oil companies have begun to pay attention to the extensive development of new information technologies. For this purpose, they mainly strengthened control over the development of the following areas:

- investment in digital technologies is not in expansion of the office equipment park, but in software;
- determining the impact of digital technologies on management processes in general;
- creation of unified information services for companies;
- development of new organizational forms of management;
- transfer of the automation management process almost from the level of operations to the level of tactical management;
- development of information systems mainly to support the decision-making process by company management.

It is clear from the experience of foreign oil companies that a special place in the digitization of management systems is related to the improvement of methods and forms of using digital technologies. In modern conditions, digitization and the development of "smart technology" guarantee, first of all, the creation and application of technical tools for personnel management, data analysis and transmission in enterprises, and the provision of economic infrastructure areas with new communication tools. Thus, the process of personnel management has a systemic nature, it involves the creation of an appropriate management mechanism, the determination of ways to solve this or that problem, the control of mutual relations between individual subdivisions, the comprehensive planning and organization of the activity of the entire system as a whole.

Scientific studies show that developed countries allocate significant financial resources to reveal the intellectual potential of the new generation and to create their world-class highly competitive technological industries and technological products. In these countries, economic "advancement" based on the end product strategy has become a tradition in higher institutions. In order to ensure the participation of students of higher schools in "unified technology" processes, companies and companies sign agreements with universities to solve the problems of innovative technologies before them and monitor their implementation. Due to the involvement of the new generation in these processes, they apply a preferential tax system to state financing companies. This experience is used in Japan, USA, Singapore, Norway, Germany, England, etc. widely distributed in countries. Thus, the main directions of the innovative development of the economy in foreign countries and the role of assessing the value of the right to a single technology are analyzed, directed and formed as a combined scientific and technical result of the interaction of identifiable and non-identifiable intangible assets of a scientific enterprise.

It should be noted that "Unit technology" is the result of scientific and technical activity of intellectual activity, which in one way or another includes inventions, useful models, industrial samples, computer programs or rules and can be the technological basis for a certain thing. In our country, in contrast to foreign higher institutions in this field, there are problems with the funding of scientific work contributions of students. Unfortunately, this field of activity remains problematic in the oil and gas sector of Azerbaijan. If the cost of scientific research, creation and application of innovative technologies in the world oil and gas sector is on average 1.5-2 dollars per ton of oil, it is 10-12 cents in Azerbaijan. Azerbaijan's oil companies lag far behind foreign oil companies in terms of the number and application of inventions and patents. For example, the Norwegian company Statoil's Patent portfolio includes about 800 inventions and 3.5 thousand patents. More than a third of these innovations are new solutions in the field of field development, and another third are solutions used in the production and sales chain. The American company Chevron, one of the world leaders in innovation, has 37,475 patents. Shell, another leader in innovation, has more than 14,000 patents.

Companies want not only to reduce costs and gain additional profits, but also to ensure the progressive development of their business in the future.

IV. Conclusion

It is especially important to create and develop new technologies and new technical means that allow to solve the existing problems in the oil industry of the Republic due to the increase of the resource base. Apparently, it is to create a whole system of pilot landfills in the extraction of "high viscosity" and "non-potential" hydrocarbons in oil fields. Such pilot projects should be planned in separate areas. It is not only a matter of separate program documents related to the creation of new technologies and the production of the technical means necessary for this, but also issues related to the process of field development and exploitation should be carried out with the sole participation of educated specialists and scientists. Thus, the issues of application of modern technologies in the development of oil and gas fields should be put in a timely manner and measures should be taken. However, in the above list of necessary solutions, the issues of who will do it and how, and from what sources of funding, should be resolved.

Famous oil industry scientists A.Kh. Mirzazanzade., V. N. Shelkachev., R. Kh. Muslumov and E. M. Khalimov, despite all the difficulties and limitations related to the operation and development characteristics of the oil industry, have repeatedly emphasized the importance of increasing attention to the issues of increasing the scientific and technical level and the efficiency of the industry in their research. The opinion of scientists that the application of methods of increasing oil production is not only a scientific and engineering task is gaining more and more understanding in the oil industry of many countries. However, it seems to us that the recommendations given in this regard are mainly based on the previously applied "linear" approach to solving scientific-technical, production, technical and organizational-economic problems. The approach of "innovative design of oil field development" proposed by R. Kh. Muslimov deserves serious attention. According to his definition, an innovative project is a scientific-research work in a certain field, which is carried out in the process of designing development. At this stage, the details of the geological structure of the object are studied, and on this basis, development technologies are selected that should fully take into account the features of the geological structure. It is to create and develop the environment that will help us to develop oil and gas potential based on a more fundamental and in some sense more realistic approach. The analysis based on the characteristics of the application of new technologies in Azerbaijan shows the following:

First priority:

- debates about what belongs to innovative technologies and what does not should not be ineffective and unnecessary in terms of evaluation for economic stimulus today.
- based on the natural dynamics of depletion of fields with large oil reserves, the transition to the organization of production from fields with more complex natural conditions should lead to changes in not only technological, but also economic norms and rules, including state regulatory methods.
- the evolution of the organizational structure of the oil industry in the direction of the gradual weakening of the monopoly role of large and integrated companies is, first of all, the selection of state policy priorities in the field of licensing, taxation, stimulation and crediting of oil companies and companies in Azerbaijan.
- the first and foremost priority for state politicians should be recognized as a comprehensive promotion of drilling new and inclined wells in all existing fields.

Second priority:

- the comprehensive promotion of the exploitation of small productive and high dilution wells is a new source of production. These wells are already a reality, they can provide the required oil production and their contribution to the total production will not be less than the contribution of all the latest technologies.

Third priority:

- compilation of national programs. These are innovative technologies programs based on individual feasibility studies and development programs for special field development projects, and programs for the development of heavy oil and bitumen resources.

The fourth priority, which is important for the implementation of the first three, is the improvement of the legal basis of oil production. First of all, it is necessary to create an open and affordable market for re-licensing and to allow the division of initial licenses both in terms of territory and object.

In order to ensure the active participation of the Azerbaijan National Academy of Sciences in the "science-education-production" chain, the High Technologies Park was established by the order of President Ilham Aliyev dated November 8, 2016. The purpose of creating the ANAS High Technology Park is the sustainable development of the economy, increasing competitiveness, innovation based on modern scientific and technological achievements, expansion of high technology areas, science, technology and innovation.

Abstract

The article describes the software package (SP) developed by the authors, which allows analyzing the social response to incidents and accidents of urban infrastructures in real time. The analysis is based on publications on the VKontakte social network. The SP performs filtering and categorization of textual information, storing data in a SQLite database, as well as quantitative and qualitative analysis of the reaction of citizens to a dangerous event. The SP automates the process of monitoring social response to emergencies, which makes it useful for the rapid response of government organizations and emergency services. The SP allows us to study, from an interdisciplinary perspective (combining the theory of technogenic safety and sociology), the interdependence of measurable damage caused by an accident of urban infrastructure and the intangible socio-cognitive damage to the community of citizens due to this accident.

Keywords: social networks, entropy, data analysis, safety.

I. Introduction

In [1, 2], the concept and approach to the entropy analysis of the social consequences of major accidents of urban infrastructures and systems are formulated based on the collection of necessary information published on social networks reflecting the details of accidents, moods, reactions and demands of society in connection with the occurrence of emergency situations. For the full-scale use of this approach, an algorithm is needed for automatic selection, collection and comprehensive socio-cognitive analysis of information purposefully extracted from social networks. This is the subject of this article.

The currently existing official methods and methods of informing the public about accidents related to the functioning of network systems and urban life support infrastructures are presented in Table 1.

There is also unofficial information, in the form of public reaction to the events, which is published on social networks. In this article, it is proposed to use social networks to monitor the state of critical infrastructures and obtain additional information about the reaction of urban society to man-made incidents and accidents [3].

II. Methods

Currently, the *VKontakte* social network is the most accessible, popular and, most importantly, legitimate platform. Therefore, it can be used as an effective tool for rapid response and understanding of public perception of incidents. *VKontakte* provides access to an extensive database, which is formed by various social groups and reflects various socio-cultural aspects of society. These multiple data are representative and can be used for a consistent analysis of public opinion and trends among different categories of the population.

Table 1: *Modern means and methods of informing society during and after natural and man-made accidents and catastrophes*

Title	Advantages	Disadvantages
Traditional media	Provide global coverage and have high credibility	Delay in the dissemination of information, limited coverage of points of view
Official reports and press releases	Information from primary sources, formal and accurate data	May be biased, delayed, do not include the public opinion
Polls and public opinion research	Allow getting structured data	May take time, limited coverage, depends on the wording of the questions
Expert assessments	High level of expertise	Can be subjective, due to a limited range of experts

VKontakte has a VK API that provides access to various data about users, communities, groups, posts, comments and other aspects of activity on the platform. Thanks to the VK API, researchers can collect statistics themselves and conduct in-depth analysis of user behavior data.

The disadvantage of *VKontakte* is data access restrictions due to user privacy settings, strict platform rules, and frequent API changes, which makes it difficult to collect data. This can lead to an incomplete analysis.

Nowadays, social networks (SN) are becoming an increasingly useful tool for improving public life. Many city administrations use SN (for example, *the Incident Management* system) as a channel through which citizens can promptly report their problem.

It seems that the SN can be used more effectively and in a multidimensional manner if regular monitoring of the SN is carried out in order to:

(1) promptly obtain information about incidents, accidents, natural disasters;

(2) monitor socio-cognitive changes in society during and after the occurrence of these incidents and accidents;

(3) promptly adopt measures to mitigate, prevent, protect and ensure the safety of citizens;

(4) carry out optimal governance in its territory, using the SN as a positive feedback in the management chain.

This work is aimed at quantitative, entropy-probabilistic analysis of social networks. The city of Kamyshlov, located in the Sverdlovsk region, was chosen to work out the methodology and algorithm for analyzing the reaction of the population to incidents in urban infrastructure. As of January 1, 2021, the city's population was 25,582. Data collection was carried out in the main community of the city in the SN *VKontakte*, where the number of participants exceeded 30,000 people.

A major accident at the central pumping station occurred on March 30, 2019. Meltwater flooded the pump's engine room, which led to the failure of two sewage pumps and the shutdown of the central water supply. As part of the study, a chronology of events was compiled:

30.03.2019	13:39 – Accident at the central pumping station
	15:00 – Shutdown of the central water supply
	16:33 – The first message about the accident (VKontakte publication)
04.01.2019	02:38 – The mayor of the city addressed the residents through a social network

	11:00 – The end of the liquidation of the accident
	23:05 – End of water chlorination
04.03.2019	22:07 – The last post about the accident
05.15.2019	7:19 – The last mention of the accident on social media.

The mayor of the city informed residents about the measures taken to restore water supply, but many citizens expressed dissatisfaction due to the lack of information about: a) the time of restoration of water supply, b) contact services, c) the causes of the incident.

Visualization of social activity after water shutdown is shown in Fig. 1. Along the abscissa axis the dates of the main events that occurred during the liquidation of the accident are posted. The ordinate axis shows the number of likes, views (in thousands) and comments under the post.

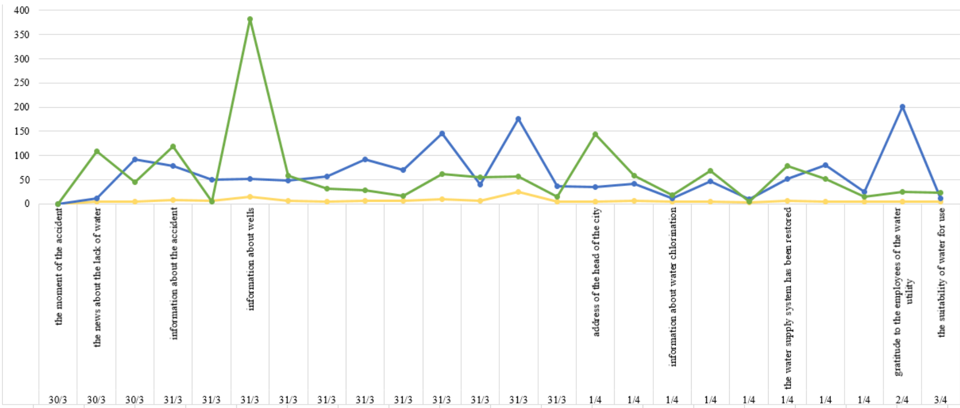

Figure 1: *User activity after the accident at the pumping station on 30.03.2019 (the number of views (in thousands) is given in yellow, the number of likes is given in blue, the number of comments is given in green)*

The greatest activity of citizens was observed on the second day after the water was turned off, when residents began to actively search for information about the possibilities of obtaining water and share information about available sources. The number of comments as a function of time is shown in Fig. 2.

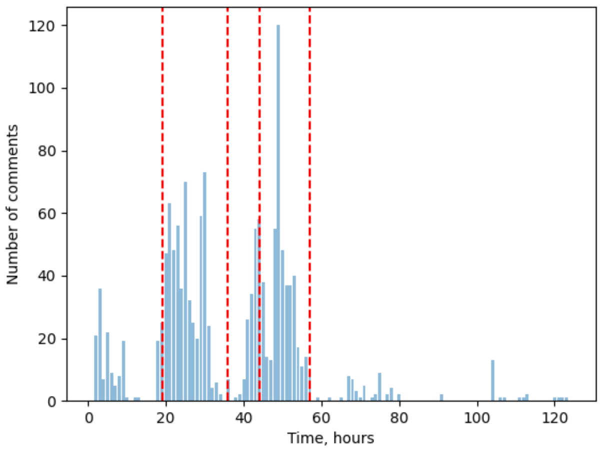

Figure 2: *The graph of the number of comments in time. The dashed lines indicate following events (from left to right): publication of information about available wells (19th hour), mayor addresses the citizens (6th hour), end of the accident liquidation (44th hour), end of water chlorination (57th hour).*

The graph shows a sharp increase in the number of comments, which peaked on the third day after the incident (April 1), when residents began to actively share their experiences, ask questions and support each other, after which the frequency of comments began to decrease, as the relevance of the topic decreases.

To improve the accuracy of the results, comments collected on social networks were classified according to their information value. The entries were divided into four groups, depending on the content of the comment, and visualized as shown in Fig. 3.

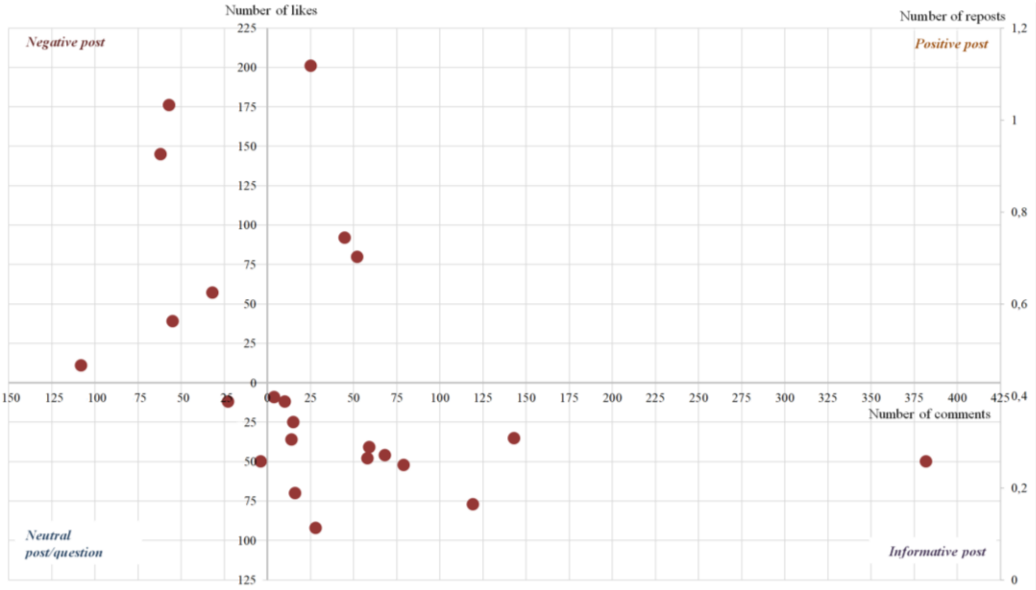

Figure 3: *A phase portrait of the accident*

Entries containing useful information are located in the lower right corner. Publications with a positive character and humorous messages are displayed in the upper right quadrant, and messages of a negative nature are displayed in the upper left quadrant. Neutral posts or messages containing a question are located in the lower left corner. The specific characteristic patterns in Fig.5 allow seeing at a glance what moods prevailed in the society during the crisis.

Fig. 4 shows the calculated entropy quanta (hourly entropy) (a) and its first derivative in time (b).

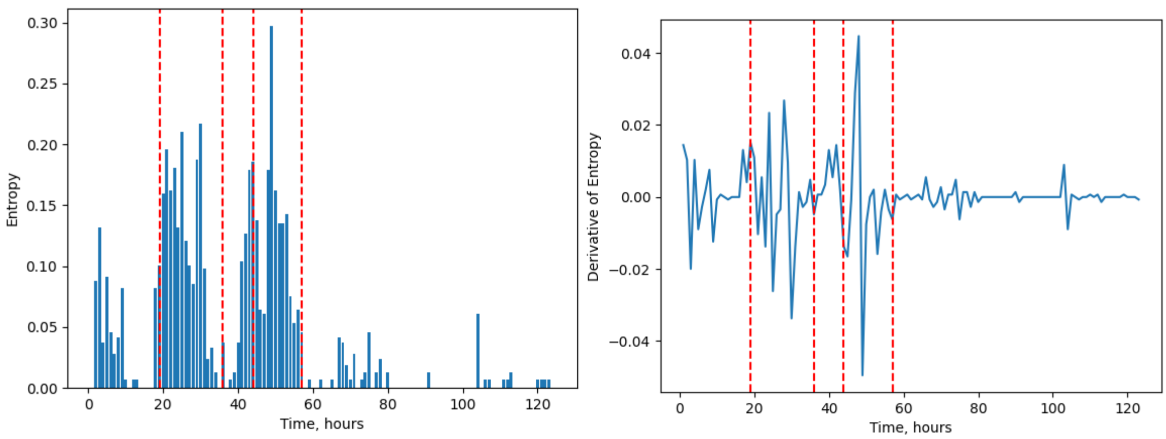

Figure 4: *Hourly values of entropy (a) and its derivative (b) in case of an accident at the central pumping station*

The initial stage of the study included: (1) manual selection of all messages related to the accident, which created a database for subsequent analysis; (2) chronological (hourly) systematization of comments about each message, and (3) their classification by content. Figure 5 shows the evolution of the probability density functions (PDF) and the entropy curve over time after an accident.

The analyzed real incident can be described as "standard", since it caused only one rapidly fading wave of social activity (five days). The main conclusions of this analysis are:

- The VKontakte social network plays an important role in the exchange of information and coordination of citizens' actions in times of crisis.

• The lack of information on the timing of the restoration of water supply and the causes of the accident contributed to an increase in social activity and discontent among the population.

• The short-term nature of the public reaction is due to the comparative speed of eliminating all the accident's consequences.

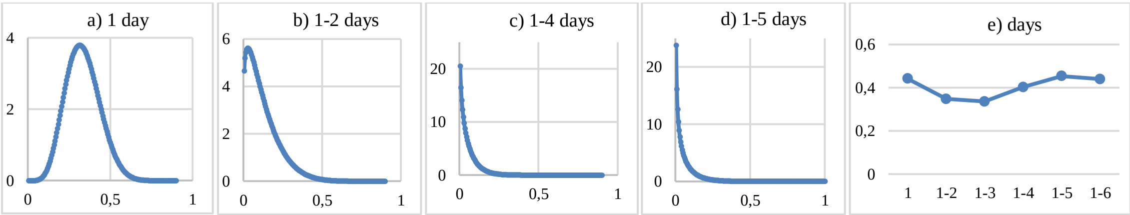

Figure 5: *a)-d) - Total PDF; e) - Change in entropy depending on the number of days that have passed since the accident*

The pilot study of the Kamyshlov population reaction has clearly shown that the use of modern technologies and communication platforms can significantly improve the quality of interaction between residents and local authorities, especially in times of crisis.

The main functions of the program for the automatic analysis of data on various incidents and events

The SP consists of the *following steps*:

1. Search in social networks for communities (public, groups, channels, etc.) by a given keyword (city name). The function is used to send a search request to the VKontakte API for groups by a given keyword. It returns a dictionary where the keys are the names of the groups and the values are their identifiers, which allows a quick find of groups of interest for further analysis

2. Filtering and analyzing publications (posts) according to a given *dictionary of keywords by category (such as "Fire", "Flood", "Terrorism", etc.)*. For this, the content of each group is parsed and checked for mentions of these words.

Additionally, it is possible to customize synonyms and variations of keywords. This makes the analysis more flexible, allowing to take into account different formulations and regional language peculiarities. For example, the expression "natural disaster" can be used instead of "catastrophe". This approach significantly increases the chances of finding important publications.

3. If a publication contains a keyword, information about it, including the text of the post, date, time, publication id, as well as the keyword mentioned in the text, is stored in the appropriate category. The program also collects and analyzes comments on these messages, which allows identifying the user reactions to specific events.

4. The program saves the result of the work to the SQLite database. Each category of data is stored in a separate table with an appropriate structure, which ensures organized storage of information. The SP contacts the SN daily and updates (replenishes) information about the incident, accident or catastrophe. SQLite provides compact storage and efficient access to data, which is critical for programs working with large amounts of information.

5. The quantitative analysis of the accumulated results includes the construction of graphs (Fig. 6) reflecting the dependence of the number of comments on time for each category of keywords. This function reads data from SQLite and visualizes the dynamics of discussions in VKontakte groups.

6. A qualitative analysis of texts is planned (identification of the mood of comments).

Each function of the program has a clearly defined task, which contributes to the modular structure of the code and facilitates the support and expansion of the program.

SP testing in the city of Yekaterinburg. ***Implementation***: a Python script using the requests, vk_api, matplotlib, numpy, pandas libraries to analyze messages from a social network.

Yekaterineburg, the capital of the Middle Urals, was chosen for SP ***testing.*** According to [4], 1,536,183 people lived in Yekaterinburg on January 1, 2024. Data collection was carried out in the groups of the city of the VKontakte social network. For the analysis, main types of incidents were selected - fire, flood, water outage, road accident, evacuation, pandemic, environmental crisis, terrorism, conflict, for each of which a dictionary of keywords was collected.

SP Advantages:

- Automation of the process of collecting and analyzing large amounts of textual information from social networks, which saves time and simplifies the real-time monitoring process.
- The ability to quickly identify and aggregate data on people's reactions to various emergency events.
- Creation of structured reports and analytics for subsequent use in making management decisions.
- Improving the efficiency and responsiveness of emergency response.
- Forecasting and prevention of emergencies.

The dynamics of user comments on the topic of incidents related to the "Fire" category from April 3, 2024 to July 31, 2024 is shown in Fig. 7. The vertical axis displays the number of comments left by users on each of the days related to the fire topic.

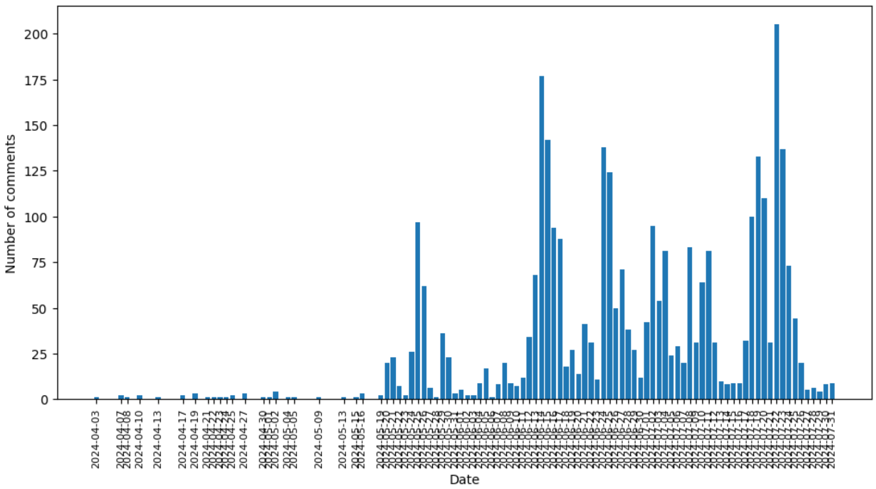

Figure 6: *A graph of the number of comments in time for incidents comments of the "Fire" category*

Judging by the graph (Fig. 6), bursts of discussion activity were observed on May 25, June 14, June 24 and July 22 (the highest peak) 2024, due to an increase in the frequency of fires. The latter is due to high air temperature, wind, dryness, active growth of grass and shrubs, and increased human activity in nature, which increases the likelihood of careless handling of fire.

The increase in user activity in the period from 11.06.24 to 17.06.24 is due to several large fires. At such moments, people tend to discuss what happened, express their feelings and get information about the situation. Peak days of activity are associated with the *size* of fires, *social unrest*; and *increased media coverage*, as users tend to follow the news and share their opinions.

User comments cover both informative and emotional aspects of the reaction to what happened. Analyzing these publications allows understanding which topics and content formats are causing an increased response from the audience that can be useful for further monitoring and analysis of incidents.

III. Results

Mathematical processing of the results

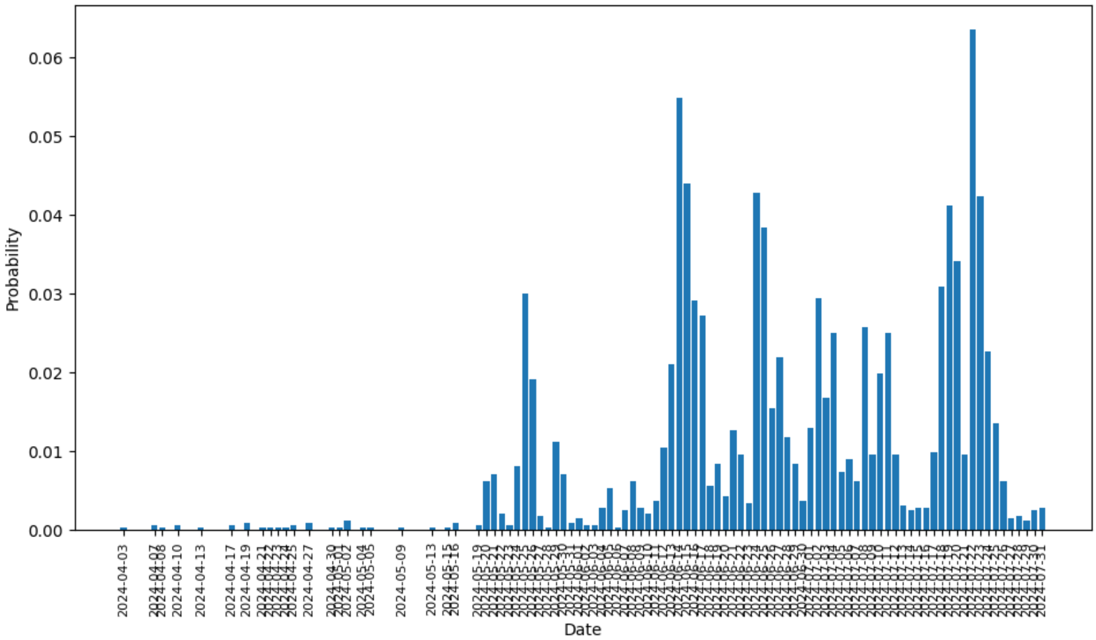

Figure 7: *A graph of the probability of comments for incidents of the "Fire" category*

The graph (Fig. 7) illustrates the probability of comments on fire publications depending on time, and shows peaks on the same dates as in Fig. 7, which indicates a direct relationship between the number of comments and public interest in incidents.

An increase in the likelihood of comments appearing at certain points confirms the importance of events taking place in a locality and their impact on social discussion.

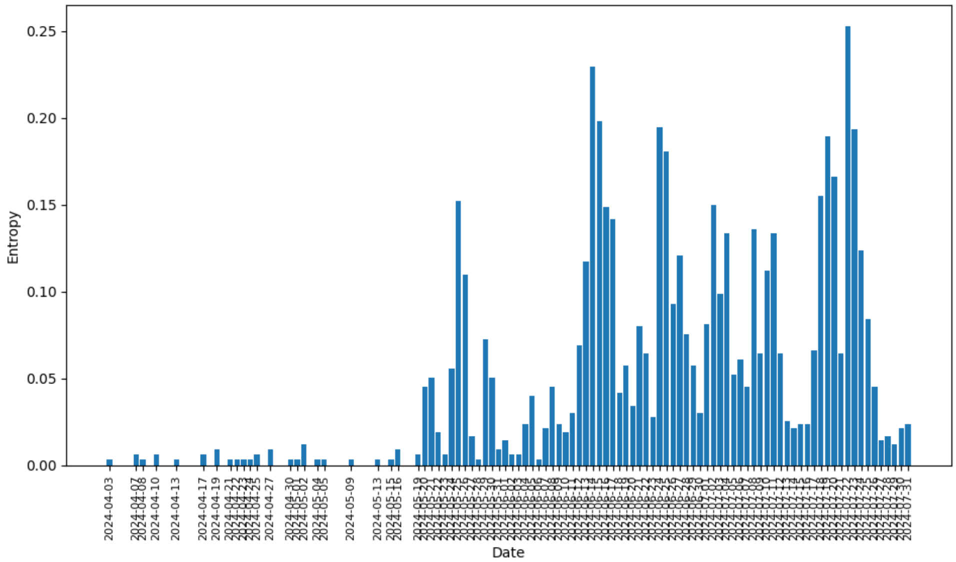

Figure 8: *A graph of the entropy of comments from time to time for the "Fire" category incidents*

The increased entropy during periods of maximum activity of citizens (Fig. 8) indicates a large number of unique and diverse opinions on the topic under discussion, which makes the audience's reaction more voluminous and saturated.

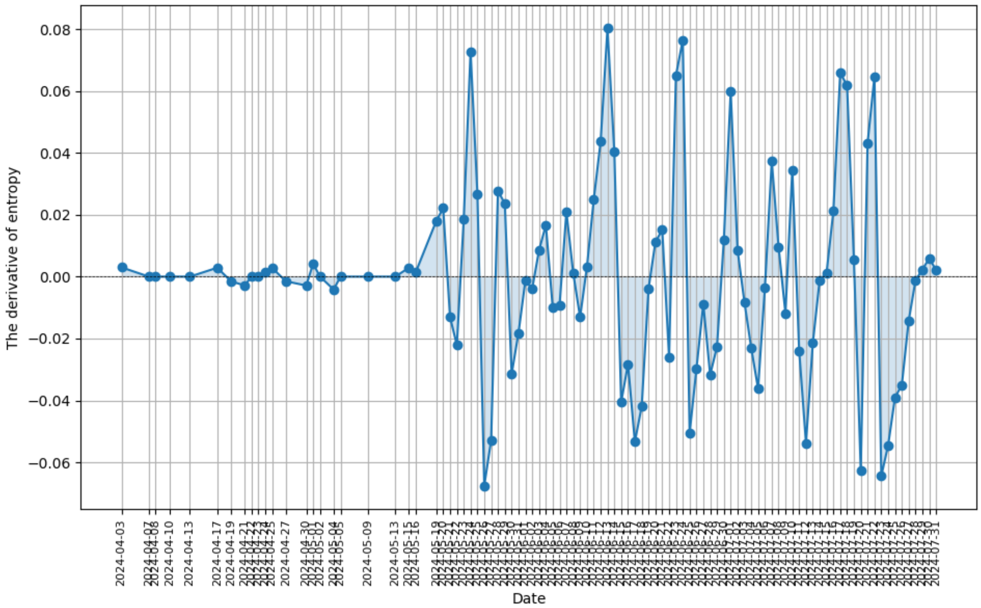

Figure 9: *Graph of the first derivative of the entropy of comments from time for the "Fire" category incidents*

The entropy derivative allows you to highlight the moments of abrupt changes in the volume and variety of comments. The points where abrupt changes in the derivative are observed may indicate significant events or changes in public opinion, which is important for crisis analysis and decision-making. These graphs provide a comprehensive understanding of the dynamics and reactions of users on social networks in response to incidents, allowing for more effective management of information flows in emergencies. The activity of users on social networks during crisis events has several important meanings:

A signal to the authorities: The high level of discussion indicates public concern, which may require government intervention.

Sentiment analysis: The number and tone of comments can help to understand the reaction of society to the incident, identify key problems and issues that need to be addressed.

Dissemination of information: Data analysis helps to track how information is disseminated among the population and which aspects of events are of the greatest interest.

The developed program is a multifunctional tool that significantly improves data processing in the context of big data flow, which makes it a valuable asset for all stakeholders. The results of testing the program showed that an automated approach to collecting, processing and analyzing data on events in the *VKontakte* SN allows:

(1) speeding up the process of monitoring incidents,

(2) better understanding the reaction of society to various emergencies,

(3) identifying key issues that concern the population, assess the emotional coloring of discussions,

(4) minimizing damage and save lives by ensuring more efficient use of resources,

(5) providing decision makers with the opportunity to make decisions that are more informed.

Combining the statistics accumulated by the SP with historical data on similar events will make it possible to create more competently a complete group of possible scenarios of incidents and accidents, which improves the quality of risk assessment of the operation of urban infrastructures.

In general, the use of this program can significantly improve the quality of real-time analysis of commercial, social and environmental information, which contributes to the creation of a more open dialogue between the authorities and society.

At this stage of SP development, the following stages of its upgrade are considered:

improving search accuracy by expanding the list of keywords; introducing machine-learning methods; expanding the functionality of the program by integrating with other social networks; improving data visualization; using sentiment analysis algorithms.

The increase in the volume of processed data leads to the problem of filtering information, and the use of data from social networks raises questions of confidentiality and ethics. It is important to find a balance between the need to respond quickly to emergencies and protecting the privacy of users. The establishment of transparent rules for working with data and compliance with ethical standards is an integral part of the effective use of SN monitoring technologies.

IV. Conclusion

The article describes the original principles and the approach to automated data analysis in social media to quantify the social consequences (unrest) that inevitably arise after each accident or natural disaster associated with the cessation/deterioration of the functioning of urban life support infrastructure. The article promotes (1) a more accurate assessment of the time of adaptation and recovery of a community at risk, (2) competent socio-economic elimination of the consequences of urban accidents by decision makers.

Abstract

In this article, decision-making models based on Z numbers were studied during the decision-making process under conditions of incomplete information, and a number of scientific and practical issues related to their application to solving the given problem were reviewed. As a result of the research, it became clear that it is not easy to form rational decision-making ability and make optimal decisions in conditions of uncertain, fuzzy or incomplete information based on existing approaches, and sometimes it is inaccurate. Thus, solving real decision-making problems, decision analysis, and systematic analysis in economics, ecology, and other fields are characterized by vagueness and partial reliability of certain data. In this regard, the Z numbers proposed by Professor Zade have a strong effect in expressing the uncertainty due to the unique structure.
This paper proposes a fuzzy approach for decision making based on Z-information based on exact computation on Z-numbers when solving decision-making problems under conditions of incomplete information. The approach is intended for hierarchical imprecise models. In the article, the models considered in relation to the research and application of decision-making models based on Z numbers are based on the processing of uncertain information and the use of word computing technology in decision-making.

Keywords: fuzzy information, fuzzy sets, Z numbers, probability distribution, decision making model

I. Introduction

Fuzzy logic theory deals with the processing of information that is vague, imprecise, fuzzy, partially true, or has no sharp boundaries arising from perception and intelligence. Fuzzy logic can be applied to linguistic evaluation, decision making, and information analysis with linguistic evaluation. Fuzzy logic, including fuzzy sets, linguistic variables, fuzzy rules, fuzzy mathematics, fuzzy database queries, computational theory of intelligence, and linguistic evaluations for computing with words, are very useful in determining the degree of uncertainty of variables.

In the researched problem, if the uncertainty arising during information processing is due to randomness, lack of information, the theory of probability, and if it is due to the inaccuracy of information, the theory of fuzzy logic is applied as a powerful tool.

The presence of uncertainty and inaccuracy in the vast majority of information in decision-making models requires greater caution and high intellectuality. Thus, it is difficult to form a rational decision-making ability based on imprecise, fuzzy or incomplete information [1].

Currently, one of the most effective and widely analyzed research problems is the problem of multi-criteria decision making. As uncertainty, impreciseness and complexity exist in the studied environment, fuzzy sets [2] will enter as one of the widely used key issues in the decision making process.

The purpose of the research in [2] is the study of representation models of uncertain information and its application to management. In this study, models of description and processing of fuzzy, imprecise information were analyzed. Issues of qualitative analysis of the researched information were considered. For this purpose, models based on objective and subjective probability theory, interval type, 1st, 2nd type and generalized fuzzy models, hybrid models were analyzed when solving decision-making problems under conditions of incomplete information, and the problems of processing uncertain information were considered.

Real decision-making problems in decision analysis, systematic analysis, economics, ecology and other fields are characterized by the vagueness and partial reliability of certain data. In recent times, the solution of a number of scientific and practical issues related to the research and application of decision-making models based on Z numbers has been considered. The considered models enable the processing of uncertain information and the use of word computing technology in decision-making. The concept proposed by Professor Zade - Z-numbers has become a center of research in fuzzy theory. Unlike previous fuzzy sets, Z numbers have a stronger ability to express uncertainty due to their unique structure [3,4].

The article [5] describes the methods of forming the uncertainty caused by the loss of information during the solution of a number of problems using Z numbers. To achieve this goal, the article examines how to convert real numbers and fuzzy numbers into Z numbers, and develops a new system of Z-linear equations.

Two processes of Z numbers ranking methods are presented in models that can efficiently use uncertain decision-making data [6]. Decision making is based on the proposed Z numbers. In this work, first Z numbers were converted into fuzzy numbers, and then ranking method using sigmoid function and sign method were used to record fuzzy numbers. In the next step, the method is extended to related Z numbers. This method was used to prioritize items and solve some patterns.

II. Models based on Z number theory

The Z number represents both the uncertain variable and its reliability. The Z number is used in decision-making, risk assessment, etc. A multi-criteria fuzzy decision-making method with stronger potential is proposed by its application in fields. Here, the assessment of each alternative by evaluators for each criterion, as well as the reliability of this assessment, is described as a Z number [3-6].

Decisions should be made based on accurate information. For decisions to be useful and effective, information must be reliable. Therefore, it is more appropriate to use the number Z. The Z number is a fuzzy number that describes the reliability of the information. The number Z is represented by the pair Z=(A,B) with two components. The first component A is the admissible constraint on the acceptance of the real-valued variable X into the fuzzy set. The second component, B, is a measure of the reliability (certainty) of the first component. Typically, A and B are described in natural language. Calculation with Z numbers is considered more important [5-7]. For example, "İnci is excellent" (Very High, Probable). The first part, "Very High" is the assessment limit of Pearl's knowledge, that is, the value of A, and the second part, "Probable" is R, which is a measure of probability that tells how true this information is.

Counting with Z numbers belongs to the field of counting with words (CW or CWW). This article introduces the concept of Z number and methods of calculation with Z numbers. The Z-number concept has great potential in many applications, economics, decision analysis, risk assessment, and predictive problems based on characteristic rules of inexact functions and relationships.

Zade introduced the concept of Z-numbers to describe vague information in a generalized form. A Z-number is a pair of fuzzy numbers $(\widetilde{A}, \widetilde{B})$. Here, $\widetilde{A}$ is the value of a variable, and $\widetilde{B}$ represents an idea closely related to a certain concept, such as certainty, confidence, reliability, degree of accuracy, and probability. Let's look at an example: Which number is more accurate for the highest age limit among people in the country: (about 100, true) or (about 90, very true). The main field of application of the proposed number theory Z will be word computing technology.

In modern activity models, for example, socio-economic, technical-medical models, it is very difficult to solve decision-making problems without taking into account the intuitions of the decision-maker. It is known that in classical decision-making models, probability values are required to be accurately described. In most real-world cases, this is impossible to achieve. In reality, especially in economics, information is subjective and imprecise. There are many approaches that describe the imprecision of relevant probabilistic information: classical numbers (level 0, for example, 1.9-17); interval numbers (level 1, for example, temperature from 20 to 25); random number (level 2, for example, male height is normally distributed around 1m 85cm); fuzzy number (level 2, eg its moral weight is "too great"); finally, Z-numbers (level 3, for example, the price of crude oil on the world market will be "high", the belief is "great"). One of these approaches is used for hierarchical imprecise models [3-7]. These models are used to account for second-order uncertainty that describes real problems. According to this approach, the opinion of the expert about the imprecise probabilities is estimated imprecisely.

III. Methods of solving the decision-making problem based on Z-numbers

It should be noted that in recent decision-making models, optimal decisions are made based on Z-numbers. Because Z is a fuzzy number that describes the reliability of information. Therefore, it is considered more appropriate to use the Z number. Lutfi Zade proposed some operations using the expansion principle for computation with Z-numbers.Diskret ədədlər üzrə arifmetik əməliyyatların ümumi strukturu.

For example, $Z_1 = (\tilde{A}_1, \tilde{B}_1)$ and $Z_2 = (\tilde{A}_2, \tilde{B}_2)$ are discrete Z-numbers that describe information about the characteristics of the random and variable. It is possible to perform various analytical calculations on Z-numbers as well as on fuzzy numbers [9-11].

$$Z_{12} = Z_1 * Z_2, \; * \in \{+, -, \cdot, /\} \tag{1}$$

First, $Z_{12}^+ = Z_1^+ * Z_2^+$ is calculated:

$$Z_1^+ * Z_2^+ = (\tilde{A}_1 * \tilde{A}_2, R_1 * R_2) \tag{2}$$

Here we describe the discrete probability distributions with R1 and R2:

$$\begin{aligned} p_{R_1} &= p_{R_1}(x_{11}) \setminus x_{11} + p_{R_1}(x_{12}) \setminus x_{12} + \ldots + p_{R_1}(x_{1n}) \setminus x_{1n}, \\ p_{R_2} &= p_{R_2}(x_{21}) \setminus x_{21} + p_{R_2}(x_{22}) \setminus x_{22} + \ldots + p_{R_2}(x_{2n}) \setminus x_{2n} \end{aligned} \tag{3}$$

Restrictions on probability distributions (4):

$$\sum_{k=1}^{n} p_{R_1}(x_{1k}) = 1, \quad \sum_{k=1}^{n} p_{R_2}(x_{2k}) = 1 \tag{4}$$

and (5) eligibility conditions

$$\sum_{k=1}^{n} x_{1k}\, p_{R_1}(x_{1k}) = \frac{\sum_{k=1}^{n} x_{1k}\, \mu_{\tilde{A}_1}(x_{1k})}{\sum_{k=1}^{n} \mu_{\tilde{A}_1}(x_{1k})}, \quad \sum_{k=1}^{n} x_{2k}\, p_{R_2}(x_{2k}) = \frac{\sum_{k=1}^{n} x_{2k}\, \mu_{\tilde{A}_2}(x_{2k})}{\sum_{k=1}^{n} \mu_{\tilde{A}_2}(x_{2k})} \tag{5}$$

is given. Here, the composition $p_{12} = p_1 \circ p_2$ is the convolution of $R_1 * R_2$, $* \in \{+,-,\cdot,/\}$.

The 'true' probability distributions p_{R_1} and p_{R_2} for $Z_1 = (\tilde{A}_1, \tilde{B}_1)$ və $Z_2 = (\tilde{A}_2, \tilde{B}_2)$ are not precisely known. Known information is given in the form of fuzzy constraints. That is,

$$\sum_{k=1}^{n} \mu_{\tilde{A}_1}(x_{1k}) p_{R_1}(x_{1k}) \ \tilde{B}_1 - dir, \qquad \sum_{k=1}^{n} \mu_{\tilde{A}_2}(x_{2k}) p_{R_2}(x_{2k}) \ \tilde{B}_2 - dir$$

This is described in terms of membership functions:

$$\mu_{\tilde{B}_1}\left(\sum_{k=1}^{n} \mu_{\tilde{A}_1}(x_{1k}) p_{R_1}(x_{1k})\right), \mu_{\tilde{B}_2}\left(\sum_{k=1}^{n} \mu_{\tilde{A}_2}(x_{2k}) p_{R_2}(x_{2k})\right) \tag{6}$$

It means that there are fuzzy sets of probability distributions p_{R_1} and p_{R_2} with membership functions.

$$\mu_{p_{R_1}}(p_{R_1}) = \mu_{\tilde{B}_1}\left(\sum_{k=1}^{n} \mu_{\tilde{A}_1}(x_{1k}) p_{R_1}(x_{1k})\right),$$
$$\mu_{p_{R_2}}(p_{R_2}) = \mu_{\tilde{B}_2}\left(\sum_{k=1}^{n} \mu_{\tilde{A}_2}(x_{2k}) p_{R_2}(x_{2k})\right) \tag{7}$$

Then, since $\tilde{B}_1$ and $\tilde{B}_2$ are discrete, the values of

$$\mu_{\tilde{B}_j}(b_{jl}),$$
$$b_{jl} \in \operatorname{supp} \tilde{B}_j, \quad j = 1,2; l = 1,\ldots,n \tag{8}$$

μ can be found by solving a series of linear programming problems:

$$\sum_{k=1}^{n} \mu_{\tilde{A}_j}(x_k) p_j(x_k) \to b_{jl}$$
$$\left.\begin{array}{l} \sum_{k=1}^{n_j} p_j(x_{jk}) = 1 \\ p_j(x_{jk}) \geq 0 \end{array}\right\} \tag{9}$$

We recognize that the "true" probability distributions p_1 and p_2 are not exact. There are fuzzy constraints μ_{p1} and μ_{p2} of p_1 and p_2 generated only by B_1 and B_2.

During the solution of the linear programming problem, we calculate the membership degrees μ_{pj} (x_j), j=1,2. Consider finding the membership degrees μ_{p1} and μ_{p2} of the distributions p_1 and p_2. It is calculated according to the formula

$$\mu_{p1}(p_1) = \mu_{B1}\left(\sum_{k=1}^{n1} \mu_{A1}(x_{1k}) p_1(x_{1k})\right)$$

using the known values of A_1 and p_1.

For the solution of the p_j th problem, each $l = 1,\ldots,n$ index is denoted by $p_{jl} = p_j$. The membership degree of p is calculated as (10):

$$\mu_{p_j}(p_j) = \mu_{\tilde{B}_j}\left(\sum_{k=1}^{n} \mu_{\tilde{A}_j}(u_k) p_j(u_k)\right), \ j = 1,2. \tag{10}$$

The probability distributions p_{1l} and p_{2l} bring the fuzzy set to the fuzzy set p_{12s}, $s = 1,...,l^2$, and their membership functions are described as (11):

$$\mu_{p_{12}}(p_{12}) = \max_{p_1, p_2}[\mu_{p_1}(p_1) \wedge \mu_{p_2}(p_2)],\ p_{12} = p_1 \circ p_2 \tag{11}$$

Here the sign "$\wedge$" is a *min* operator.

According to (12) in the next step

$$A_{12} = A_1 * A_2 \tag{12}$$

the fuzzy price is calculated:

$$P(\tilde{A}_{12}) = \sum_w p_{12}(w)\mu_{\tilde{A}_{12}}(w) \tag{13}$$

In the last step,

$$P(\tilde{A}_{12})\ P(\tilde{A}_{12}) = b_{12} \tag{14}$$

we calculate the probability measure b_{12}, where p_{12} is known. However, we only know the fuzzy constraint described by the probability function.

Thus, $P(\tilde{A}_{12})$ is a B12 fuzzy set with $\mu_{\tilde{B}_{12}}$ membership function:

$$\mu_{\tilde{B}_{12}}(b_{12s}) = \sup(\mu_{p_{12s}}(p_{12s}))\ ,\ b_{12s} = \sum_k p_{12s}(x_k)\mu_{\tilde{A}_{12}}(x_k) \tag{15}$$

Consequently, Z_{12} is calculated as:

$$Z_{12} = Z_1 * Z_2,\ * \in \{+,-,\cdot,/\}\ \ Z_{12} = (\tilde{A}_{12}, \tilde{B}_{12})$$

Figure 1. shows the probability measure indicating that the knowledge assessment threshold is correct on a 10-point scale (A).

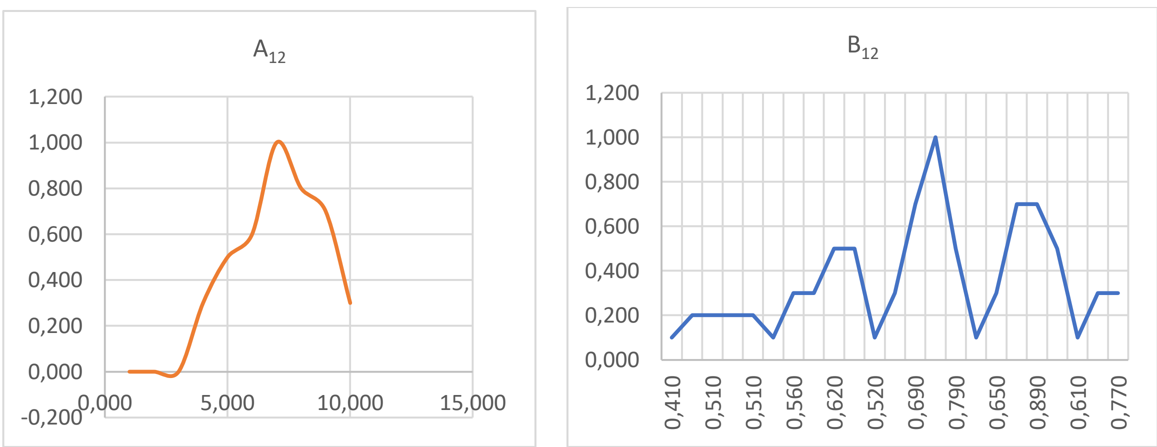

Figure 1: *Results of summing discrete Z-numbers*

IV. Result

This article presents an approach for Z-information based decision making based on exact computation on Z-numbers under conditions of incomplete information. This approach is based on finding a probability measure by applying arithmetic operations on discrete Z-numbers that describe information about the properties of random variables X_1 and X_2. This approach is widely used in solving management issues in the field of economics.

Abstract

The article focuses on the study of the filtration performance of modern respirator models when exposed to welding and electroplating fumes containing ambient particles smaller than 10 microns (PM_{10}). The low filtration capacity of most modern respirators with respect to nano- and microparticles was revealed. Respirator filtration performance can be affected by a number of factors including: different filtration mechanisms, environmental parameters, filter material properties, number of respirator layers used, packing density, fiber loading density, fiber diameter, aerosol particle type and size, aerosol flow rate and concentration values, and additional factors from different human activities. Modern filtration materials and respirators are not able to provide 100% protection against the penetration of the smallest particles of industrial aerosols into the body. Respirators with multi-layer protection, fitted with carbon filters, have the highest capture capacity.

Keywords: industrial aerosols, particulate matter, filtration capacity, electroplating, welding, nano- and microparticles, respirators

I. Introduction

Ambient air pollution by particulate matter has become a serious public health hazard in many regions [1]. Some of the main sources of pollution are exhaust gases from motor vehicles, welding, and electroplating.

According to the standard definition of nanoparticles by the U.S. National Nanotechnology Initiative (NNI) [2] and ASTM E2456-06 [3], particles smaller than <100 nm should be considered ultrafine particles. These particles are highly permeable, capable of penetrating deep into the alveoli, beyond the natural airways of bodies and settling in the lower respiratory tract [4]. These particles can trigger serious diseases such as respiratory symptoms, lung cancer, and silicosis depending on the components of particles [5]. Ultrafine particles of industrial aerosols pose toxicological hazards depending on their surface characteristics [6].

Therefore, there is a high demand for respiratory protective devices. Variants of respiratory protective devices are a face mask and a respirator.

A face mask is a loose-fitting, disposable device that creates a physical barrier between the user's mouth and nose and potential pollutants near an air pollution source. A respirator is a personal air cleaner equipped with a filter that provides a tight fit to a person's face [7]. There are several key factors that affect respirator performance: (a) filtration, (b) flow resistance (i.e., air permeability), (c) ergonomics, and (d) continuous operation in a given environment. Additionally, it is important to note that using respirators does not prevent oxygen from entering the human body. And there is no significant difference in the oxygen saturation of human lungs when using respiratory protective devices (P> 0.05) [8].

The filtering and separation of submicron-sized contaminants is a major challenge today. The development of modern respirator filter materials that would effectively capture suspended nano- and microscale particles requires an innovative approach. Nanofibers [9], 3D printers [10], and additive technologies [11] for manufacturing filter materials can significantly advance the technological development of respiratory protective devices.

Filter efficiency depends on several factors. It improves as the size of the filter material fibers decreases due to the high mechanical ability to trap the smallest particles suspended in the ambient air. However, it is the shape of the fibers, rather than their calculated average aerodynamic diameter, that is the dominant factor in the deposition mechanisms in the tested respirators [12].

The present study is focused on the research of the trapping characteristics of respirators exposed to aerosols of electroplating origin. Electroplating is a source of emission of heavy metal oxides into the air. It is known that exposure to aluminum, arsenic, lead, cadmium, and manganese in the workplace can increase the risk of numerous neurophysiological changes in workers and can trigger the development of Parkinson's and Alzheimer's diseases [13].

Among the technological processes of modern industrial production that have been studied so far, those that pose the most significant hygienic risks are the following:

- In electroplating it is the electrochemical process of nonferrous metals etching [14]. Used daily, this is one of the main technological processes in electroplating workshops for manufacturing parts from nonferrous metals.

- In welding production, it is manual arc welding of metal plates (construction steel, S = 8 mm) using electrodes with rutile covering, diameter 3 mm [15]. Emissions from manual welding are almost equivalent to the air emissions from the underwater welding [16].

For the listed technological processes, it was decided to perform a comparative analysis of the trapping characteristics of filters in 10 modern respirators in real production conditions.

It is important to understand that different types of respirators and masks have their advantages, disadvantages, capabilities, and limitations. However, for each specific type of industrial production, the most suitable and versatile masks can be developed that can provide a high level of industrial safety for workers.

In addition to the safety requirements for viral aerosol filtration tests, one of the major problems that researchers currently face is the inability to simulate or simulate true aerosol filtration scenarios through laboratory experiments, field tests, and in vitro / in vivo studies [17]. There are few studies on the effectiveness of respirators in capturing suspended particles of industrial aerosols in real production conditions [18].

For this reason, a full-scale experiment was conducted in real production conditions of electroplating and welding shops. This work is aimed at investigating the penetration ability of welding and electroplating fume particles through the filter material of modern models of respirators. For this purpose, we selected the most popular models of respirators for welding production and compared the trapping characteristics of their filter elements in real production conditions. In contrast to the works of other researchers [19], in this experimental work, only samples of filter materials were used to assess the penetration ability, not the whole respirators.

II. Experimental

Measurement of the quantitative composition of PM

The quantity of airborne PM was measured using the AeroTrak Handheld Particle Counter 9306 (TSI Incorporated, USA). This sampler meets all the requirements set out in ISO 21501-4.

Continuing the previous research of air pollution by electrochemical processes from the hygienic point of view (depending on the levels of $PM_{0.3}$ and PM_{10} in the air) [20, 21], we chose to further study the influence of the nonferrous metals etching and manual arc welding using electrodes with rutile covering on the trapping characteristics of filters in modern respirators (Table 1, Figure 1).

Filtering facepiece respirators (FFP) are commonly used in workplaces due to their low cost, comfort, ease of use, and sufficient effectiveness.

Table 1: *The list of personal respiratory protective equipment used in the experiment*

No.	Respirator/mask model	Technical specifications
1	Filtering facepiece respirator with breathing valve “Stayer Master 11118”	Protection class: FFP1 Material: textured polypropylene Manufacturer: Kraftool I/E GmbH, Germany
2	Filtering facepiece respirator with breathing valve “Zubr Expert 11160”	Protection class: FFP1 Material: textured polypropylene Manufacturer: Zubr OVK, Russian Federation
3	Filtering facepiece respirator “DEXX 11103”	Protection class: FFP1 Material: polypropylene Manufacturer: Zubr OVK, Russian Federation
4	Filtering facepiece respirator with breathing valve “Zubr Master 11163-2”	Protection class: FFP2 Material: textured polypropylene Manufacturer: Zubr OVK, Russian Federation
5	Filtering facepiece respirator with breathing valve “Rutex F1101”	Protection class: FFP1 Material: electret filtering material Manufacturer: Rutex, China
6	Filtering facepiece respirator “KN95”	Protection class: FFP2 Material: non-woven fabric and meltblown filter fabric Manufacturer: Jinhua Han Ye Daily, China
7	Filtering facepiece respirator with breathing valve “Istok”	Protection class: FFP2 Material: polyethylene foam Manufacturer: Istok, Russian Federation
8	Filtering facepiece respirator with breathing valve “Briz-1102(Y-2K)”	Protection class: FFP1 Material: polyurethane foam Manufacturer: Briz-Kama, Russian Federation
9	Facepiece elastomeric air-purifying respirator “RPG-67” with filter type A1B1	Protection class: FFP1 Material: woven fabric, charcoal filter Manufacturer: GK Rim, Russian Federation
10	Medical face mask	Material: nonwoven three-layer SMS (spunbond, meltblown, spunbond)

Air samples were taken at a distance of 1 m from the source of air pollution (Figure 1) at a constant height of 1.5 m corresponding to human breathing level.

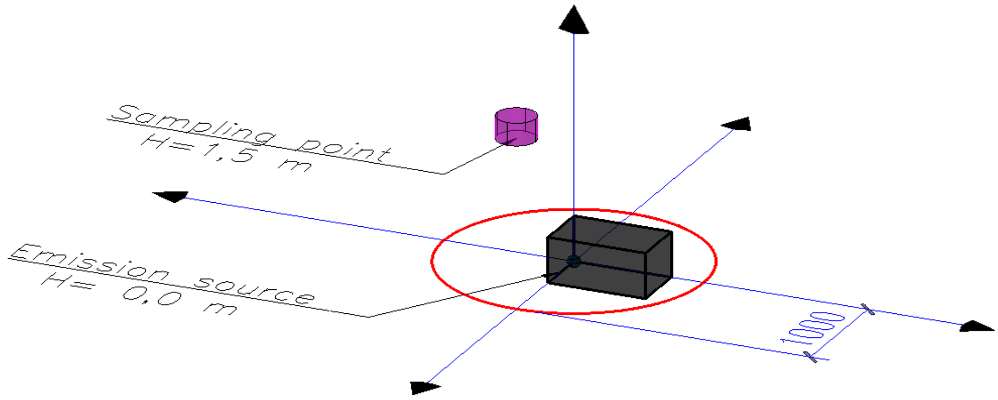

Figure 1: *Location of the sampling point in the production shops*

Two series of sampling were performed: using filters of 10 models of respirators for welding and electroplating.

Mass concentration of airborne PM

To determine the content of fine particles of industrial aerosol in ambient air, a series of air samples were taken using the aspirator-type sampler "Aspirator PU" (JSC Khimko, Russia) with filters from 10 modern respirators.

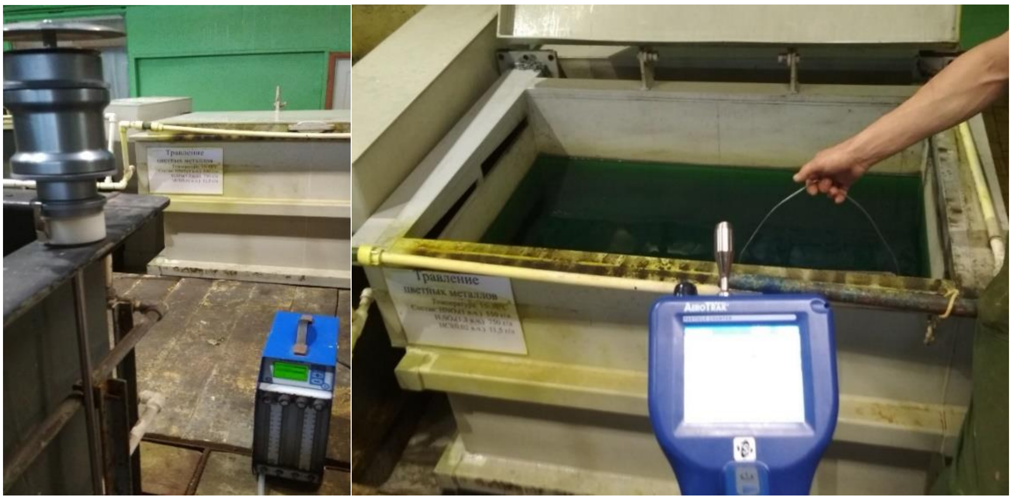
In this sampler, instead of normally used aerosol filters based on a Petryanov filtering cloth made of fibrous perchlorvinyl fabric (Gorky Kimry Factory, Russia), we used filter material taken from modern models of respirators and cut to the size fitting the sampler (Table 1).

During the experiment, this sampler was equipped with an additional attachment for sampling particles of the PM_{10} fraction, taken from a similar aspirator LVS 3.1 (Ingeniero Nobert Derenda, Germany). The range of particles for filters in this attachment is from 0.45 μm to 10 μm. The upper limit (PM_{10}) was chosen because it poses the greatest danger to human health, being the cause of respiratory diseases [22]. This reflects the current trend in the field of control of substances suspended in ambient air [23].

Before sampling, the filters were pre-dried in a TC-1/20 thermostat (Russia) for 24 hours at 40 °C (Fig. 2), then each filter was weighed three times on electronic balance CAS CAUY-120. Arithmetic mean weight was determined for each filter.

Figure 2: *Preparation of filter materials in the thermostat*

The samples were taken at the sampling points shown in Fig. 1, 3 and 4 at 1 m from the pollution source (electroplating bath or welding operator).



A) B)

Fig. 3: *Sampling air probes in the electroplating shop. A) air sampling, B) PM sampling.*

The installation height of the sampler corresponded to the level of human respiration – 1.5 m. The sampling time was 1 min for each filter. The air temperature during the experiment was 18 °C, the wind speed was 0 mps (samples were taken inside the workshop). The volume of air pumped through the sampler was 2.8 m^3/h. Filters with samples of particulate matter were transported to the laboratory of REC "Nanotechnology" of the Polytechnic Institute FEFU for further determination of the concentration of PM_{10} particles.

A) B)

Figure 4: *Taking air and PM samples during welding. A) Measuring instruments, B) Welding process*

Dust content in the air was measured by weighing the filters on electronic balance CAS CAUY-120 before and after sampling. Each filter was weighed three times and arithmetic mean was determined. The resulting difference in the weight of filters before and after the air sampling procedure corresponded to the settled mass of particulate matter, including the PM_{10} fraction.

Electron microscopy of PM

To visualize airborne particles deposited on respirator filter material, a state-of-the-art stereo microscope Zeiss Stemi DV4 (Germany) was used. The microscope's features include 30x image magnification with viewing angle up to 60°.

This microscope is equipped with a high-intensity illuminator that offers three illumination modes to produce a clear image of the sample. The Zeiss dual-lens zoom system ensures excellent sharpness and high-resolution images.

Two 50x50 mm samples were cut out from each filter of 10 respirator models, corresponding to "before" and "after" the experiment on measuring the concentration of deposited industrial aerosol particles. The fibers of each filter were photographed using electron microscopy.

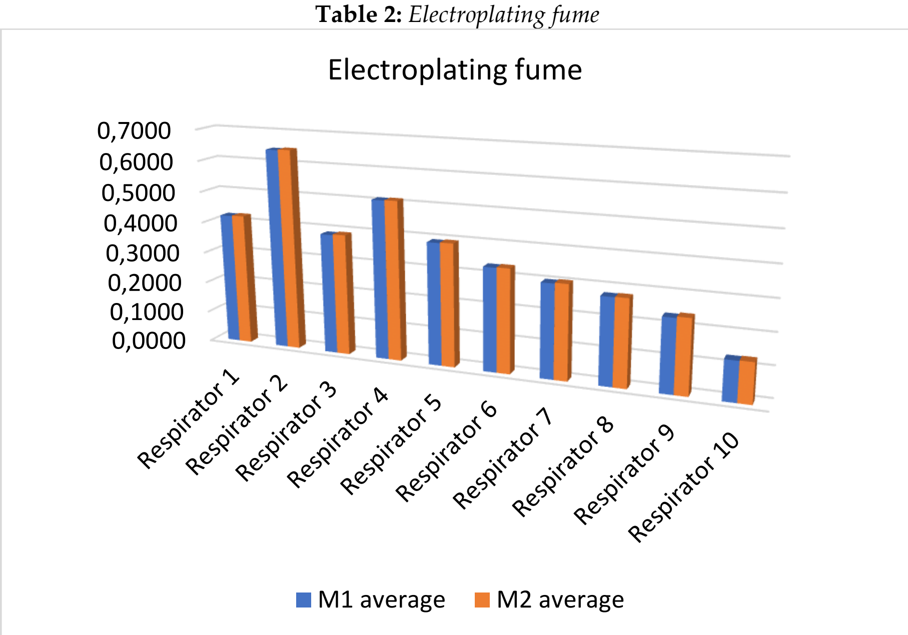
III. Results and discussion

It is known that penetration of industrial aerosol particles through the filters of respirators increases with the flow rate regardless of the type of particles, and the particle size is a significant factor influencing the penetration of combustion aerosol particles [24]. For this reason, the experiment was focused on measuring particles up to 10 μm in size, which have the greatest penetrating ability [25] and ability to settle deep into the lungs of welders and workers of related professions. Tables 2—5 summarize data on mass concentration and quantity of welding fume and electroplating fume particles.

The issue of identifying ineffective personal respiratory protective equipment is particularly relevant in the context of the pandemic [26] and the shortage of masks and respirators on sale, as well as appearance on commercial market of uncertified products with low effectiveness or even fake models [27—29].

Mass concentration of airborne particles of electroplating fume deposited on filters

Table 2: *Electroplating fume*



According to the data obtained (Table 4), the trapping capacity of filters in respirators varies depending on the PM fraction. Table 2 shows the weight data of respirator filter samples before and after the series of experiments. M1 values describe the weight of the filter sample before the experiment and M2 values – after pumping 2.8 liters of air through the respirator filter.

To obtain the values of the mass of deposited solid particles originating from electroplating aerosol, their content was recalculated to the level of 1 m^3 of air pumped through the filter.

The highest mass of deposited particles was found in respirator No. 9 (RPG-67 with filter type A1B1). This respirator can trap up to 1.6 mg when pumping 1 m^3 of air through its filter.

The second place in terms of the mass of industrial aerosol particles deposited on the filter is respirator No. 3.

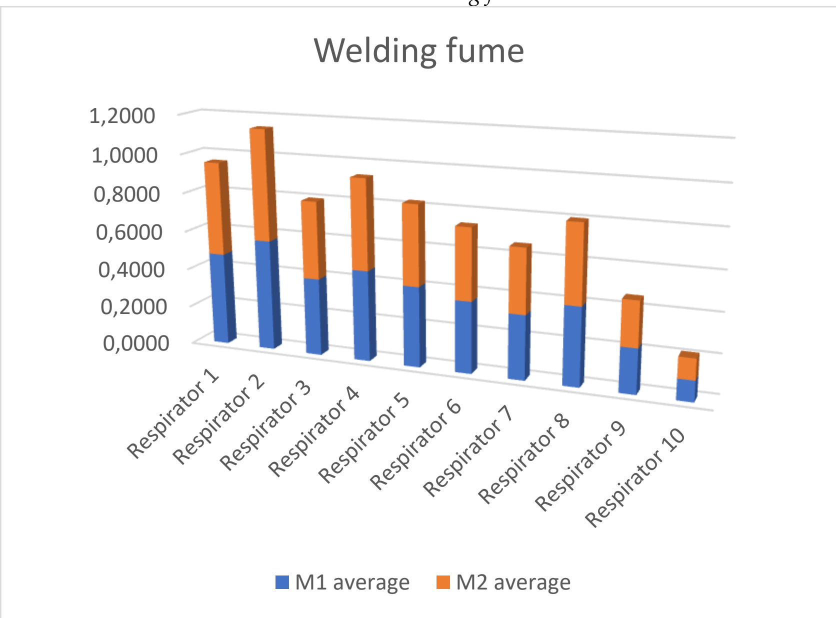
Respirators No. 2 and No. 5 show average values of deposition of industrial aerosol particles. The values for these samples range from 0.8 to 0.9 mg/m^3. Respirator No. 4 demonstrates the best trapping ability for PM_1 and PM_3 fractions. Respirator No. 5 (closely followed by respirators No. 3-7), has the highest mass of deposited PM_5 and PM_{10} particles.

Respirators No. 8, 10, 6, 4, and 1 are ineffective in trapping airborne particles of electroplating aerosol and practically do not prevent particles from freely penetrating the filtering material of respirators. The values of deposited particles on filters of these respirators range from 0.5 to 0.7 mg/m^3.

As can be seen from the data presented in Tables 2, 3, the mass concentration of airborne PM deposited on the filter elements of respirators in the electroplating shop is several times higher than the concentration of particles in the air of the work zone in the welding shop. This fact may be due to the finer size of solid particles of the welding fume, which easily overcome the filtering barrier of respirators.

Mass concentration of airborne particles of welding fume deposited on filters

Table 3: *Welding fume*

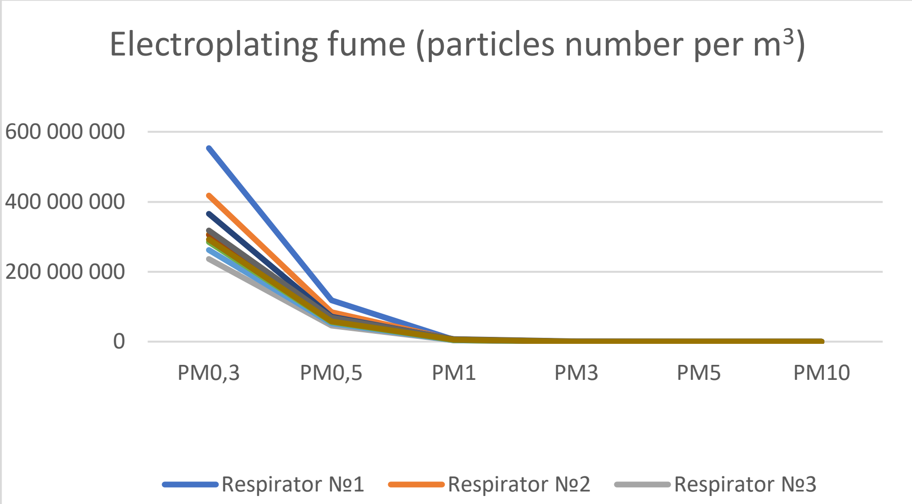


The obtained data indicate that the majority of respirators used in the experiment had low particle trapping efficiency. Respirators No. 2—6 (group 1) are barely effective in capturing solid particles of welding fume. Additionally, other 2 models of respirators: No. 8 and No. 1 (Group 2) have average efficiency against other tested respirators.

The highest mass of deposited particles was found in respirator No. 9 (RPG-67 with filter type A1B1). This respirator has several protective layers – woven fabric and charcoal filter. The filter material of this respirator trapped from 2 to 10 times more particles compared to samples from the first and second groups, correspondingly.

Quantity of airborne PM

Table 4: *Electroplating fume (particles number per m³)*



Filters do not degrade or recover after the exposure to industrial aerosols stops. Therefore, the aerosol penetration measured at any time after exposure should be equal to the maximum obtained using the respirator [30]. It should be noted that since the filter material samples were used as filters in the aspirator, they demonstrated 100% efficiency, and there was no air leakage through the end seal in different head positions when the respirator was placed against the worker's face.

The filtering efficiency of respirators depends largely on the size of solid particles, and the penetration of any dust through the mask will be critically influenced by its fractional composition.

Considering that 30-100 nm particles have the maximum penetrating ability [31], respirator No. 3 should be selected as having a clear advantage. Respirator No. 3 is most effective in trapping particles of the smallest fractions: $PM_{0.3}$ and $PM_{0.5}$. This respirator has a higher particle trapping capacity for these particle sizes compared to other respirators ranging from 20% to 234%, depending on the model.

The maximum content of aiborne PM was registered at the beginning of the experiment, with values being an order of magnitude higher than those for other repetitions. The content of particles of the smallest fraction ($PM_{0.3}$ and $PM_{0.5}$) exceeds similar indicators of other models of respirators.

Table 5 below summarizes the measurement values for the experiments performed in the welding shop.

It is known that unlike the ultrafine fraction, larger particles (e.g., 800 nm) are almost completely trapped by the filter material in respirators with medium and high protection class [32]. That is why the numbers of nano- and micro-size particles were counted before they were deposited on the filter material inside the aspirator. The number of fine particles in welding fume ($PM_{0.3}$ fraction) reached hundreds of millions particles per 1 m³ (from 316 to 980 mln particles), which exceeded the number of PM_{10} particles several hundred-fold (from 19 to 42 thousand/m³). Nano-range particles are the most hazardous for human health as they can easily bypass alveolar protection of lungs, deeply penetrating into human internal organs and causing chronic diseases of the upper respiratory tract [33].

Compared to electroplating, a greater number of airborne particles were formed in the second half of the sampling experiment series rather than at the beginning.

As expected, the lower mass fraction of particles deposited on respirator filter elements during welding is due to their smaller size. The cells of the filter elements significantly exceed the dimensions of particles that easily penetrate the protection of respirators and penetrate into the respiratory organs. This is evidenced by the higher number of suspended particles of the $PM_{0.3}$ and $PM_{0.5}$ fractions during welding in comparison with the electrochemical process (Table 5). The average values of PM during welding are on average 1.5÷2 times higher in comparison with the electroplating process.

According to the results of electron microscopy, the samples of filter material from respirators No. 3 and 9 demonstrate the best trapping properties. Solid particles of industrial aerosols deposited on the filter are clearly visible (they have a dark color). The electron microscopy results correlate with the number concentration of airborne PM confirming the mechanical trapping ability of the respirator filtering material (Table 2).

The photographs of filters from respirators No. 8, 10, 6, 4, and 1 before and after the experiment are very similar because no deposited particles of industrial aerosol can be observed. These photographs and the data in Table 2 confirm the low sorption and filtration capacity of these respirators. Therefore, these respirator models are ineffective in trapping airborne PM originating from electrochemical processes in electroplating production.

The results obtained indicate the possibility of penetration of the smallest particles of industrial aerosols through the protective filtration barriers of personal respiratory protective equipment. It is known that prolonged inhalation exposure to industrial aerosols contributes to the emergence and development of occupational respiratory diseases in welders, electroplaters and workers of related professions. Prolonged exposure to industrial aerosols provokes the development of fibrogenic processes, mainly silicosis, dust bronchitis, pleurisy, pneumonia and asthma [34]. The risk of occupational diseases increases with each year of work experience, and at the age of 12-15 years the maximum rates of development of chronic diseases are reached in welders, electroplaters and workers of related professions [35].

The solution to this problem may be the introduction of new materials as filtration elements in personal respiratory protective equipment, such as composites, nonwovens, or with physical properties of magnetic fields to improve trapping characteristics.

IV. Conclusions

The results obtained indicate that there is a significant variation in the filtration efficiency of the filter elements in different respirator models.

Respirator filtration performance can be affected by a number of factors including: different filtration mechanisms, environmental parameters, filter material properties, number of respirator layers used, packing density, fiber loading density, fiber diameter, aerosol particle type and size, aerosol flow rate and concentration values, and additional factors from different human activities [17] and the fit of the respirator to the human face [36, 37].

According to the data obtained, the trapping capacity of filtering material in respirators varies depending on the fraction of airborne PM. The maximum efficiency is demonstrated by respirator No. 9 with a multilayer filter element which traps particles of the smallest fraction much better than other models used in the experiment. It should be noted that in experimental conditions, the maximum trapping characteristics of the filtering material of respirators were considered, without any leakage on edges where respirators fit to the worker's face. For models with the low trapping capacity of the filtering material (respirators No. 8, 10, 6, 4, and 1), it may be a factor that compensates for the disadvantages through better ergonomics and tight fit of the respirator to the face of the worker in real production conditions.

It should be noted that choosing the most effective respirator model that captures the maximum amount of airborne particles, thereby preventing their penetration into the human body, which can lead to occupational diseases with prolonged exposure, can solve the problem of reducing the incidence of disease among electroplaters, welders and workers in related professions. However, polymer materials used in the production of respirators and masks are usually not biodegradable which can cause serious environmental problems in most countries where waste disposal systems are ineffective. Therefore, respirator models with non-woven and non-synthetic materials have great prospects for the future if they achieve a high trapping capacity and low airflow resistance.

The results obtained for the filtration efficiency of the filter materials allow us to conclude that respirators with combined multi-layer filter elements are the most effective. Since we did not take into account a number of respirator factors, such as the tightness of the mask to the face, long-term preservation of working characteristics, and based only on the filtration capacity, it is possible that other respirator models will be more effective in real production conditions due to unaccounted for advantages.

Abstract

The article is devoted to the study of the natural risk impact on the operation of railway industry facilities using a Bayesian network model in the GeNIe Modeler software package. Statistics of railway accidents from floods over the past few years have allowed to identify the main parameters of the model, the network structure is based on the experience and expert opinion of railway industry workers and foreign researchers. The results show that natural and climatic factors can cause serious disruptions in the operation of railway transport, and in the case of dangerous goods, create conditions for developing cascading accidents. The developed Bayesian model can be used in integrated planning and railway system management during floods.

Keywords: railway transportation risk, Bayesian network, climate change, flood

I. Introduction

According to the estimates of the United Nations Intergovernmental Panel on Climate Change extreme climate events (fires, floods, intense rainfall) are a serious threat and will occur more often, leading to disruption of various infrastructures. Nowadays, the scale of natural disasters far exceeds the human capacity to cope with them.

Rail transport is a critical infrastructure. The railway failure leads to economic damage from the displacement of the delivery time of goods, the cost of restoring equipment, potential loss of life and environmental damage. When moving dangerous goods through the territory of urban agglomerations, there is a high risk of accidents, especially in combination with weather anomalies.

Thus, the flooding in Armenia caused by intense rains in May 2024 led to the death of 4 people, the evacuation of 300 people and the wash away of more than 2.5 km of railway tracks. In August 2023, 1000 m of the Baikal-Amur mainline and 10 power transmission towers were destroyed in Buryatia as a result of cloudbursts, more than 300 people were evacuated. In 2018, due to the heat at the Pskov-Tovarny railway station, sulfuric acid leaked from the tank, by chance no one was injured.

Natural risks cannot be managed; they can only be analyzed and quantified. Railway transport is more susceptible to natural risks compared to other modes of transport, because it is less flexible in spatial terms [3]. Measures to combat climate impacts are being developed on a global scale and may be useless at the regional and local levels, as they do not take into account socio-economic opportunities, limited resources, geographical and climatic features of a particular territory. The situation is aggravated by the negligence of the staff, and wear and tear of the equipment.

Many studies have been devoted to the problem of the nature influence on the engineering system functioning. Ostankovich I. et al. [15] conducted an analysis of the extreme temperatures and snowfall risks to assess the state of the Dutch railway network. Alabbad et al. [5] performed a spatial analysis of railway infrastructure facilities (marshalling yards, bridges and crossings) during seasonal floods in Iowa. Struzhkova et al. [17] investigated the influence of permafrost on the railway network functioning. The dependence of the working capacity of the Serbian railway personnel on weather conditions was studied in [1].These studies show that the assessment of natural risks in regions exposed to extreme weather conditions is of great importance for maintaining the operability of the railway network.

In this work, a prediction and detailed analysis of a railway accident as a result of the impact of a natural factor (flooding) was performed based on the previously developed hybrid Bayes network in the GeNIe Modeler software package for a railway accident (159 variables) [4] (Figure 1). The model was tested using the example of the spring leash of the Ural River in 2024 in Orsk, the city where the last flood occurred almost 70 years ago.

(the parameter names are hidden in order to preserve intellectual property)

II. Research methodology

2.1 Climate influence on the operation of railway infrastructure

The railway track is the most vulnerable element of the railway, because it is most affected by external factors. The most common meteorological factors are temperature and precipitation (snowfall, heavy rains, ice, etc.). Table 1 contains a list of possible impacts.

Table 1: *Natural phenomena and possible consequences for railway facilities [13]*

Natural hazards	Negative consequences
Geological Mudslides, landslides, flushing, subsidence, dust storms, avalanches, frost upheaval, waterlogging of territories, erosion (destruction of rocks by water, wind, man), abrasion (destruction of shores by waves)	Damage/destruction of railway tracks, embankments and slopes, falling power lines/trees, etc., blocking of railway stations
Geophysical Earthquakes, volcanic eruptions, karsts	Damage/destruction of railway tracks
Meteorological Storms, hurricanes, tornadoes, squally wind, whirlwinds, large hail, snowfall, showers, blizzard, fog, sleet, frost, drought, abnormal heat/frost, frequent change of warm/cold days, melting permafrost, lightning	Deformation and warping of railway tracks, sagging of power lines, overheating/electronic failures, fires on slopes, equipment failure, speed limitation, shortening of equipment life, the need for cooling equipment, damage to contact networks, power surges, breakdowns of alarm devices, centralization, blocking, falling of power lines/ trees, etc., freezing, icing, increased fragility of rails, freezing of switches, blocking of railway stations, accumulation of snow along railway tracks
Hydrological Flooding, high water, congestion, wind surges, rising groundwater levels, earthquake flood, typhoons, storms, changes in the strength and direction of waves	Inundation, damage to railway embankment and slope, erosion of bridge supports, railway tracks, contact networks, water penetration into underground structures, tunnels, flooding of coastal infrastructure
Wildfires Forest, peat, steppe, underground fires of combustible minerals	Thermal effects on all metal, combustible elements of railway equipment

Table 2: *Possible flood factors*

Natural and climatic	Non-climatic (organizational)
The amount of the winter precipitation, the water supply in the snow cover, the temperature condition before the start of spring melting, soil moisture in autumn, the snowmelt intensity, the terrain of the riverbed, the slope of rivers, the landscape of the area (forest belts, steppe or wooded soil with underlays), the presence of constrictions in the riverbed, the presence of obstacles to the flow, the earthquake impact, landslides, landslides, rising groundwater levels, deep freezing of the soil, snow reserves and its rapid melting, terrain.	The water level in the dam site, the technical condition of hydraulic structures, the distance from the dam, insufficient water discharges, design errors, poor-quality construction and maintenance, reduction of river capacity in the area of bridges, narrows, buildings in the floodplain, losses as a result of business activities, economic development, urban planning.

In this study, the focus is on floods, since the railway is the most vulnerable mode of transport to external influences [11]. In addition, floods occupy the first place among natural disasters in Russia in terms of frequency, area of distribution and total material damage [14]. The scale of floods depends on many natural and organizational factors (see table 2). It is necessary to take into account their synergistic effect, because in combination with each other, these factors increase the risk of an accident.

2.2 Data availability

The Bayesian approach makes it possible to combine frequency data with domain knowledge. Numerical values of probabilities can be extracted from databases, based on expert opinion, or determined by a combination of the above. Experts point out serious problems in collecting statistical information on the railway state due to climate impacts [5, 9, 11, 14]. This is due to the following factors:

- Complexity of meteorological observations, poor knowledge of the water regime of rivers, lack of hydrological observation posts, especially at the regional and local levels
- Lack of a clear algorithm for reporting railway accidents
- Deliberate misrepresentation of information by responsible persons in order to get away with it
- Inconsistency or inaccuracy of the data

Beyond that, the railway accident registration as a result of the effects of floods is not conducted anywhere. Therefore, this paper combines two sets of statistical data on floods and railway accidents [8] when creating two interconnected Bayesian networks. The first network is designed to calculate the probability of an accident as a result of flooding. The results of its calculates are partially used as input data for the launch of the second network, which determines the type of possible railway accident and the amount of possible damage.

2.3 Construction of model

The first data set contains more than 200,000 records on 50 features of past floods. The second data set includes more than 100,000 records of railway accidents abroad in 160 parameters from 1975 to 2022. These initial data were processed in the Python programming environment: cleared of omissions, invalid character and zero values, duplicates; all quantitative characteristics were given in the International System of Units, some of them are categorized for the convenience of building Bayesian models. After performing an Exploratory Data Analysis, only a few of the recorded data parameters were identified.

Flood data includes the following 19 features out of 50: relief drainage, drainage systems, river management, deforestation, urbanization, climate change, dam quality, siltation, incursions, effective disaster preparedness, vulnerability of coastal areas, landslides, deterioration of infrastructure, loss of wetlands, inadequate planning, political factors, probability of an accident.

Data on railway accidents include the following 18 features out of 160: month of accident, type of accident, dangerous cars, evacuated people, visibility, weather conditions, type of track, total tonnage, derailed loaded freight cars, derailed loaded passenger cars, cost of track damage (Figure 2).

The formatted data was imported into the GeNIe software package [10]. The columns in the data files correspond to variables (future nodes of the network), and the rows (records) correspond to various values of these variables. Continuous variables have been discretized. Based on the knowledge of the subject area [1, 2, 16, 17], the basic structures of Bayesian networks have been created. The Greedy thinning algorithm was used as the main algorithm for structural learning.

Figure 2: *Fragment of the data set on railway accidents*

As a result, two Bayesian models were obtained, including a number of factors described in Table 2. Figure 3 shows that climate changes do not directly affect the probability of an accident, but are significant with a low organization of services in case of an accident (see Figures 3 and 4).

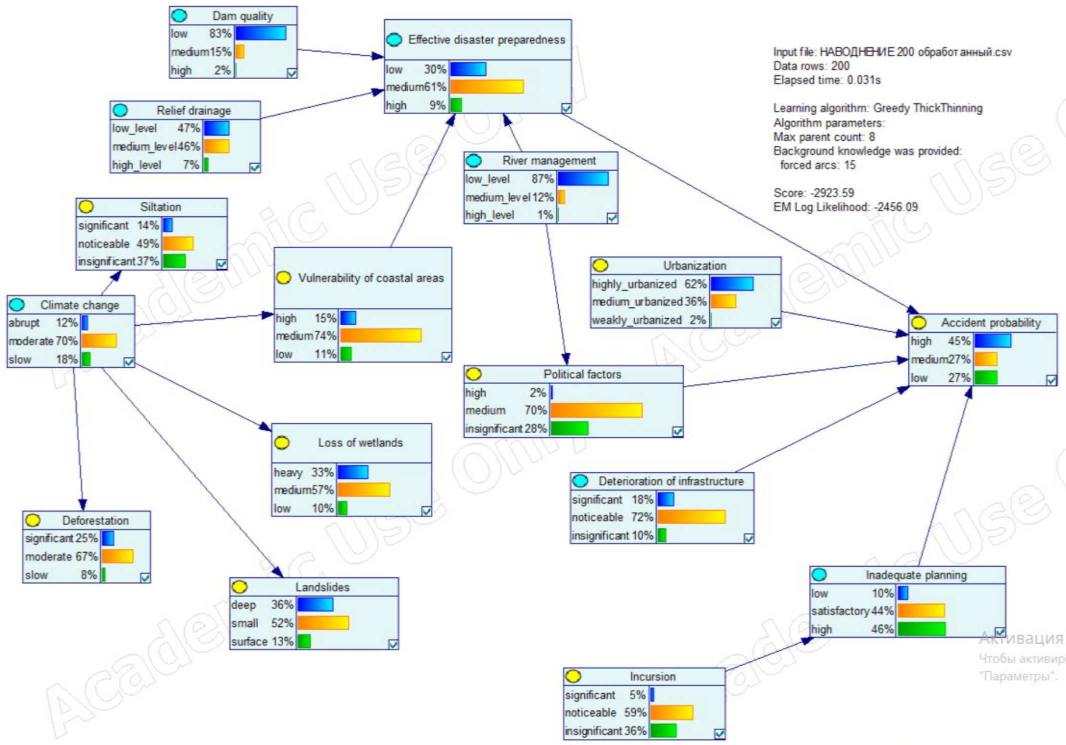

Figure 3: *Bayes network for calculating the probability of an accident*

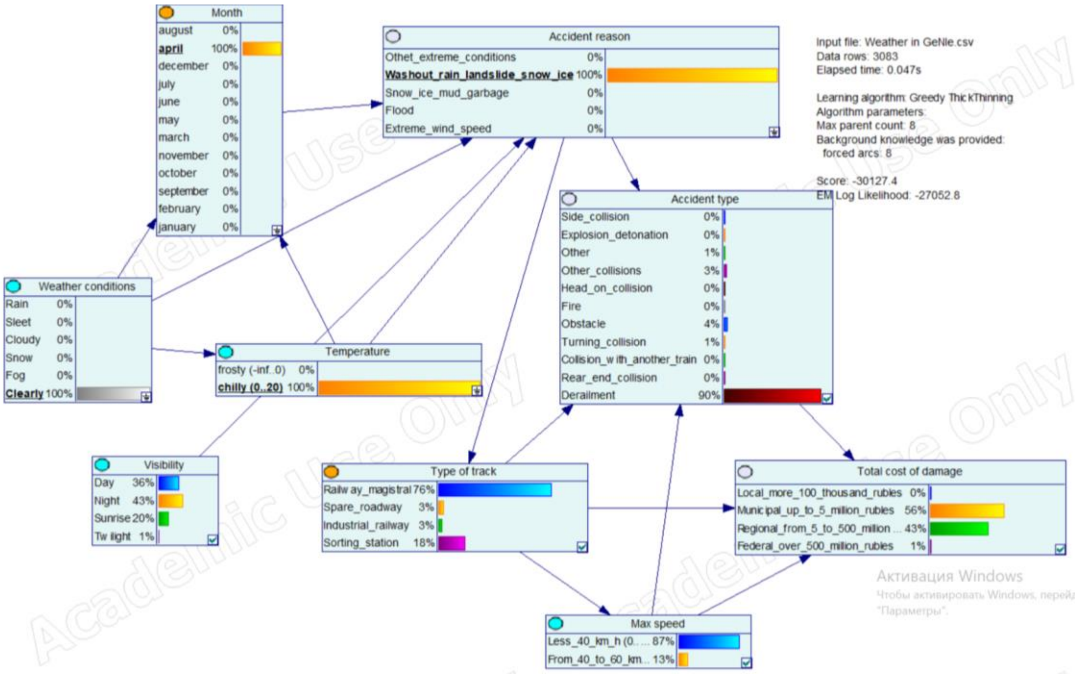

Figure 4: *Bayes network for determining the consequences of a railway accident*

2.4 Evaluation of model accuracy

The model accuracy was evaluated in two ways. Based on the first set of flood data, a new data file was generated to verify the accuracy of the first model with 200 records. The second model was evaluated by 10-fold cross validation. In this case, the original set of data on railway accidents was divided into 10 equal parts. The first nine parts participated in the training of the model, the last 10th part was used as a test sample. A graphical representation of the model accuracy is presented in the form of ROC curves with an overall accuracy of 89 and 75% for the main nodes of the network, respectively (Figure 5). Curves located above the diagonal and tending to the upper left corner represent good forecast results.

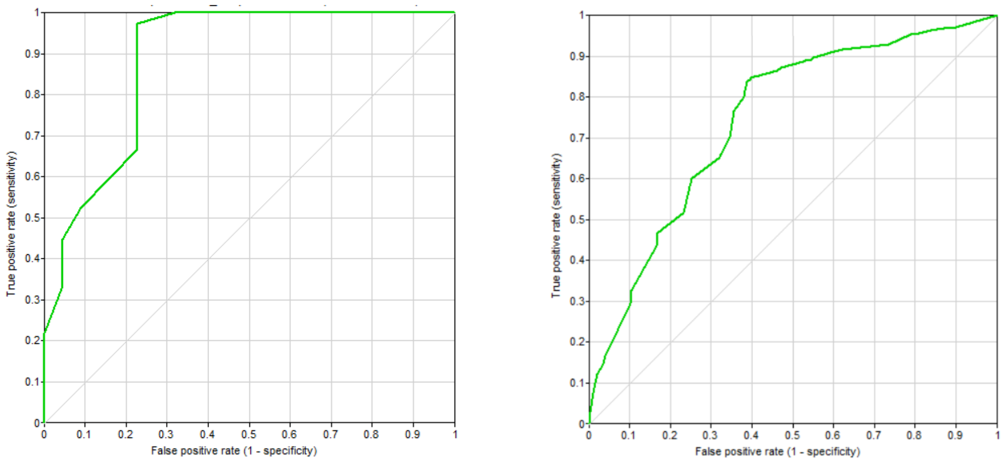

Figure 5: *ROC-curves for nodes ''Accident probability = high'' and '' Total cost of damage = Regional''*

II. Results

3.1 Case study

In April 2024, a number of Russian regions were exposed to catastrophic flooding caused by the spring flood on the Ural River. The city of Orsk in the Orenburg region suffered the most, for which flooding is a rather rare phenomenon. The last ones happened in 1922, 1942 and 1957. In Orsk, as a result of the destruction of the dam, about 6.6 thousand residential buildings, summer cottages and vegetable gardens were flooded (Figure 6). The total damage is estimated at more than 21 billion rubles. The flood led to the destruction of buildings and communications, the cattle death, the erosion of sewers, urban landfills, cemeteries and animal burial grounds, which created a threat of contamination of drinking water and human diseases. This real flood case was chosen to demonstrate the calculations of the resulting Bayesian networks.

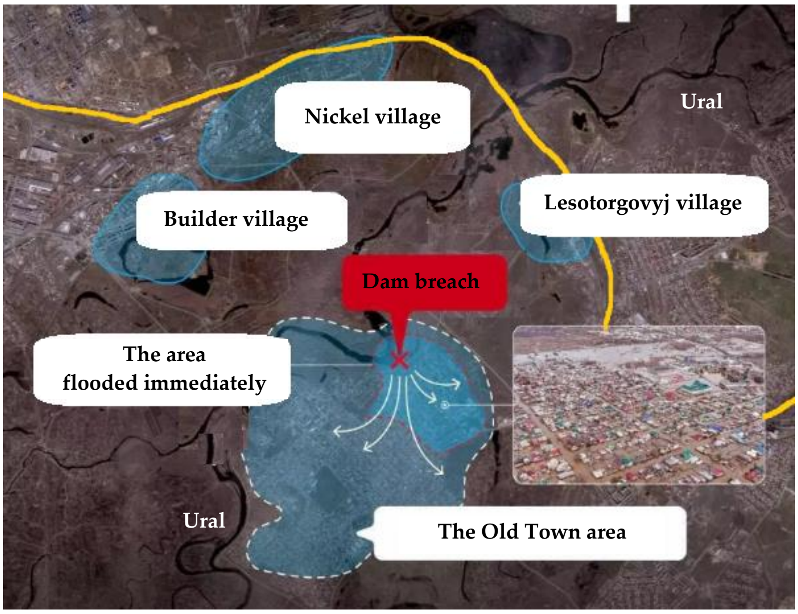

Figure 6: *Scheme of flooding in Orsk (the railway location is indicated in orange) [18]*

3.2 Analysis of calculation results

The probabilistic models have been edited for the case under consideration. The calculation of the networks showed updated posteriori probability distributions in the nodes of the networks. Further, the mutual influence of network parameters was analyzed.

Sensitivity analysis showed that the critical factors in flooding are "Disaster preparedness", "Level of urbanization", "Deterioration of infrastructure", which significantly affect the main target variable "Accident probability". This means that even minor changes in the colored nodes have a significant impact on the risk of an accident (Figure 7).

The ranking of flood factors showed that the most critical of them were "River management at zero level", "Poor quality of hydraulic structures", "Deterioration of infrastructure" (Figure 8). If the city's leadership had taken these factors into account, it would have been possible to prevent the developing of the spring flood up to a federal emergency.

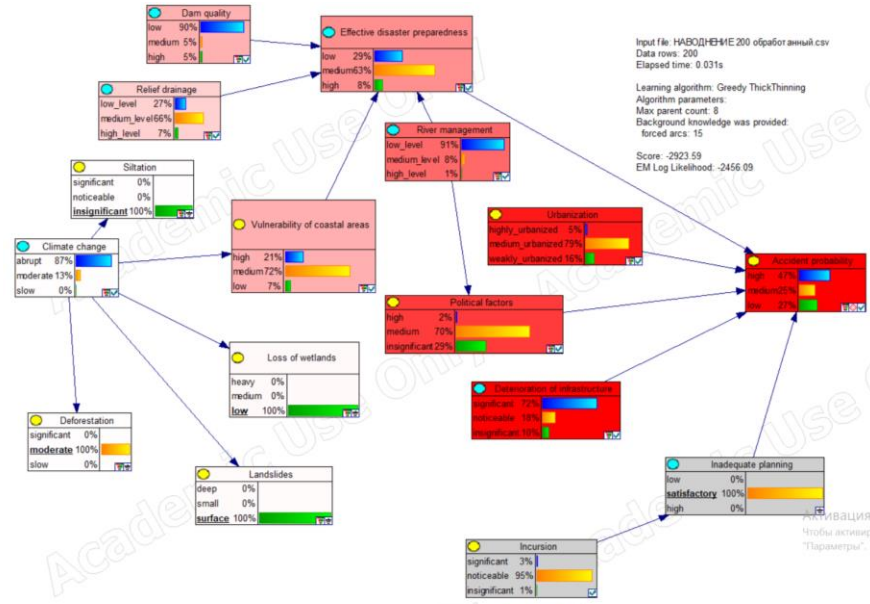

Figure 7: *Sensitivity analysis of the main node*

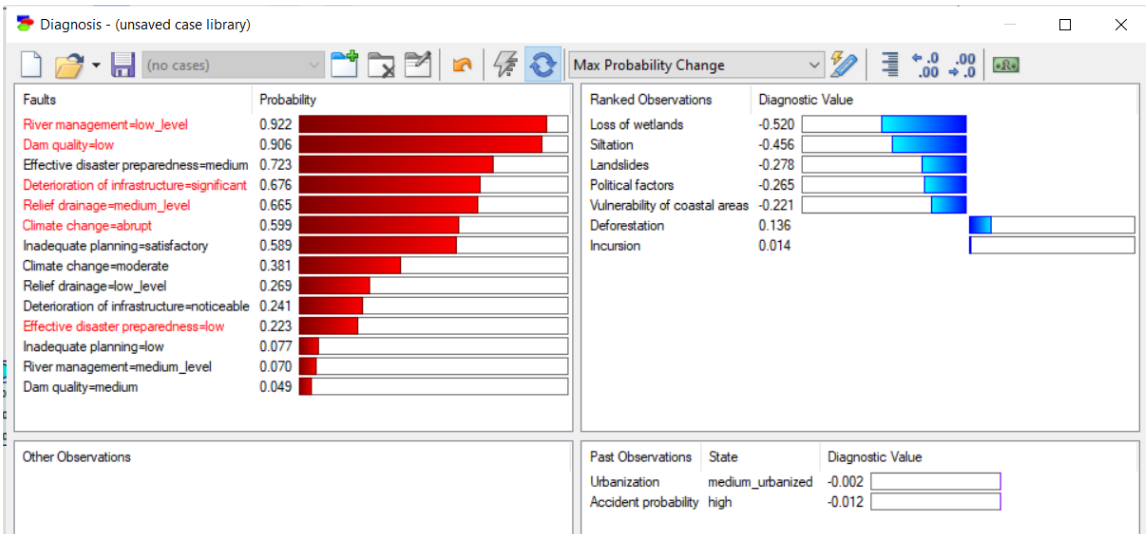

Figure 8: *Ranking of flood causes*

The developed networks are only an approximate model for predicting flood risk, since they are based on foreign statistics without taking into account the location of the area. At the moment, the accumulated scientific material is not enough to create a more complex and realistic flood model in the region under consideration. The study should be continued in the direction of collecting data covering a wider range of climatic factors and creating a database on accidents on domestic railways.

In the qualitative assessment of flood factors in Orsk, it is worth noting the following:

1. Features of the Ural River. The river has the largest water content among European rivers due to the uneven flow. The difference in river flow between high-water and low-water years can be 10 times. The depth of the river is small, but due to elevation differences in the source and mouth of the river, its speed can reach up to 10 km/h. [6]

2. High rate of urbanization. The massive construction of residential and commercial buildings, roads in the floodplain led to a 4-fold reduction in the natural floodplain.

IV. Conclusion

The article discusses the features of natural accidents on the railway due to floods in the context of climate change. The use of two thematic data sets (on floods and on railway accidents) is proposed. As a result, two Bayesian networks have been created to predict railway accidents in flood conditions. Using the example of a real flood in Orsk, the effectiveness of using the Bayesian approach for a comprehensive analysis of a railway accident as a result of a flood, including sensitivity analysis and ranking of flood causes with color visualization, is demonstrated.

The proposed probabilistic models can help in creating strategies for managing the consequences of natural risks on the railway, especially in cases of dangerous goods transportation. This will increase the reliability of the railway infrastructure in the face of climate change.

Among the preventive measures, the following should be highlighted:

- A ban on the construction and management of economic activities in floodplain areas and lowlands, which represent a permanent potentially dangerous area for urbanism
- Creation of a continuous monitoring system in vulnerable regions to collect climate data and take into account the impact of climate change in the design and operation of railway infrastructure

Acknowledgment

I would like to express my gratitude to my scientific supervisors Timashev Svyatoslav Anatolyevich and Poluyan Lyudmila Vladimirovna for valuable advice in carrying out the research and recommendations on the article design.

Abstract

In the paper, based on the analysis of accidental oil spills from pipelines, a grapho-analytical method was proposed for the correct determination of the amount of hydrocarbons spilled into the environment in different modes. During the accident, it was proved that the opinion about the free flow of oil into the environment is not correct due to the fact that the atmospheric pressure was not created at the maximum point of the track profile, but at the accident site (hole).
Currently, there are almost no correct methods for multiphase flows, unlike single-phase flows, in normative documents and literature sources.
Taking into account that the determination of which part of the oil flows from the pipeline during real accidents is very important for risk analysis, studies were carried out on the basis of the compressed profile of the oil pipeline.
In the paper, accident-oil spills, as well as the conditions under which it is possible to make 3-5% of the volume of the pipeline in the free flow mode, and the complete emptying of the pipeline are defined.

Keywords: oil spill, free flow, hydrostatic pressure, vapor elasticity, condensed profile, grapho-analytical method

I. Introduction

Although oil spills during the operation of oil and gas pipelines that do not result in explosions, fires and pollution of water sources are not considered very serious accidents, it is important to determine the amount of oil spilled in order to assess the losses and environmental impact. Explosion and fire monitoring and assessment of such accidents must be done. In this regard, the development and application of methods for correct determination of the volume of oil or gas spilled into the environment due to any impact from pipelines in different regimes deserves special attention.

If we are talking about short pipelines, then the simplest method for determining the volume of liquid and gas is the method based on the average flow rates of the phases, taking into account the speed of movement of the mixture. The results of such a calculation result in a significant reduction of the volume of the liquid phase in the pipeline, and an increase of the volume of the gas, on the contrary. However, experience shows that during multiphase flows in relief pipelines, there is always a ballast volume that is not displaced by gas. This ballast volume can be small at high speed of movement of multiphase mixture, and much more at low speed values.

According to the current methodology [1, 2], the volume of oil spilled into the environment during accidents in oil pipelines is determined according to the following expression:

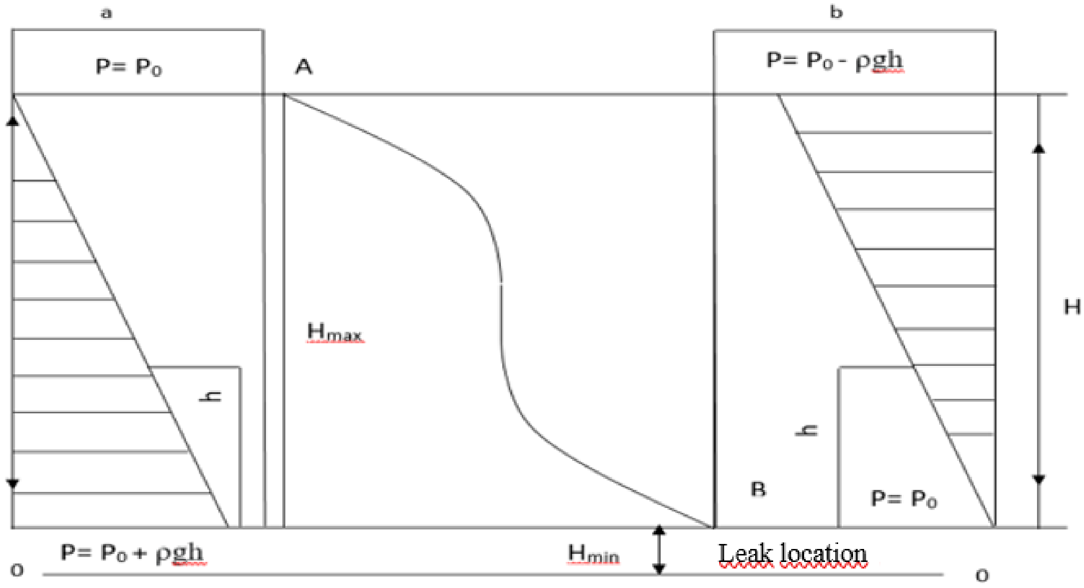
$V = V_1 + V_2 + V_3$

Here: V_1- the volume of oil discharged (dispersed) in pressurized mode. This volume is the volume of oil flowing during an accident until the pumps stop working (within 2 minutes); V_2- is the volume created due to unpressurized (free) flow, it is the volume of oil spilled during the time between stopping the pumps and closing the valve in the pipeline; V_3-is the volume of oil flowing through the emergency hole in free flow mode.

It should be noted that the main oil or oil product pipelines are equipped with an automatic system, so the flow time in the pressurized mode does not exceed 2 minutes (the pump and outlet drawer are closed at the same time and within 2 minutes). After the pumps are stopped, the oil flow time in the free-flow mode is assumed to be almost zero, since the valve is closed at the same time. The most interesting problems are observed during the determination of the volume of oil flowing in the free-flow mode after the valve is closed. This volume depends very much on the detection and localization of the place of damage and collapse of the pipeline.

II. Methods

In order to solve the mentioned problem, 2 points (A and B) are marked as the maximum and minimum on the profile of the pipeline. Then the graph of pressure distribution in the intended part is constructed. At this time, the crash site (hole) is considered as the minimum point of the profile. The pressure distribution graph constructed in this way is shown in figure 1.



a and b – on the false and true model, respectively

Figure 1: *Distribution of hydrostatic pressure in the leaking part of the oil pipeline*

Then it is assumed that the pressure varies along the profile of the AB part of the oil pipeline according to the graph (a) in figure 1. At this time, it is considered that the atmospheric pressure in the pipeline corresponds to its maximum point (A). Then, accepting the distribution of pressure along the height according to the law P = $P_0 + \rho g h$, the oil flow rate from the emergency hole is determined by the following formula known from hydraulics:

$$v = \sqrt{\frac{2P}{\rho}} = \sqrt{\frac{2(P_0 + \rho g h)}{\rho}} \quad (1)$$

Here: ρ- density of oil, kq /m^3 ;P_0 –atmospheric pressure, Pa; g- free acceleration, m/s^2; h- current height, m.

From Fig. 1, it can be seen that, the atmospheric pressure in the accident oil pipeline is not created at the maximum point of the profile as in option (a), but at the minimum point of the profile, i.e. at the accident hole (B). The pressure of the liquid column below the crash hole increases because the pressure of the liquid column is added to the atmospheric pressure. On the other hand, going up from the hole, the pressure in the pipeline decreases to the pressure of the liquid column at the height h (Fig. 1, b). Thus, it is found that in non-pressurized flow, since the intra-pipe pressure is equal to the atmospheric pressure in the cross-section of the crash hole, it will not be possible for the oil to flow freely to the environment. The free flow of oil from the accident hole will be possible when the hole is not located under water. When this hole is dry, only a part of the pipeline between the near crossing point and the emergency hole will slowly and gradually loosen. The rest of the oil in the pipeline will not be able to flow freely (without pressure). In this case, the relief is usually provided by compression with a piston or by opening holes in the pipeline at all crossing points (to allow air to freely enter the pipeline).

In general, the currently existing mathematical models for calculating the amount of oil and gas spilled as a result of accidents are adopted according to the hydraulics of single-phase flow of liquids and gases through holes and pipes [2÷4]. Appropriate assessment and calculation methods for multiphase flows are almost non-existent in normative documents and literature sources.

Let's examine the possibility of complete discharge of the pipeline section when the valves are closed at the beginning and end. Using the principle of continuity of flow, it can be confirmed that, in principle, it is impossible to completely empty the pipeline. This also goes against the laws of physics. So, the place of the oil removed from the pipeline must be filled with another cold medium (for example, atmospheric air or oil vapors).

It should be noted that oil evaporation is possible due to the difference between the atmospheric pressure and the pressure inside the pipeline when the heights are different along the pipeline route. That is, the pressure drop in any section of the pipeline leads to the following equation:

$$P_0 - \rho g h = P_{v.e} \quad (2)$$

Here, $P_{v.e}$- oil vapor elasticity pressure, Pa; h - is the height of the oil column from the accident hole, m.

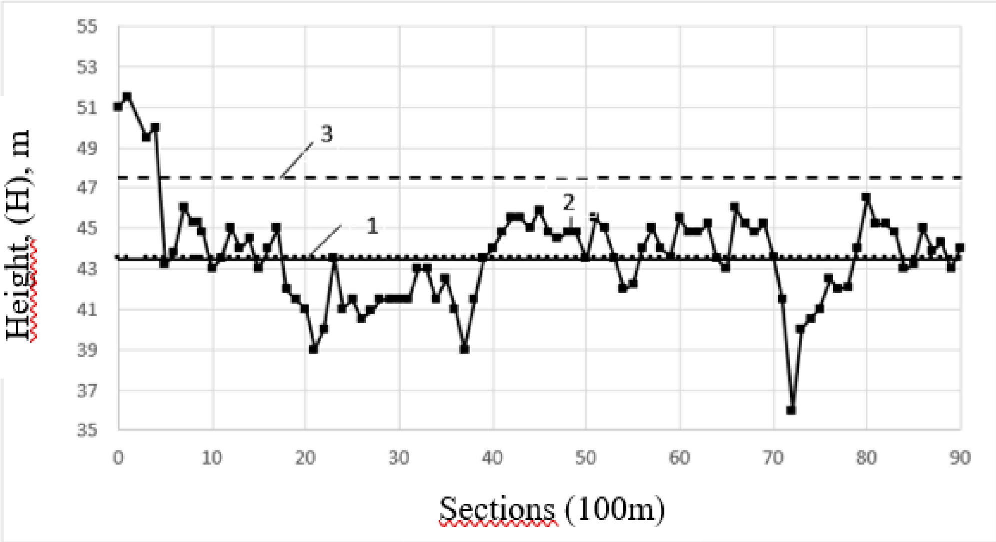
Where condition (1) is met, the oil begins to "boil" and the vapor phase separates from it, which replaces the liquid phase flowing through the pipeline.

Taking into account that determining which part of the oil flows from the pipeline during real accidents in practice is also very important for risk analysis, let's examine the issue based on the condensed profile of the oil pipeline (Figure 2). The parameters of the considered oil pipeline are as follows:

- pipeline length L=8.5 km;
-pipeline diameter D=0.7 m;
- pipeline volume V_P=3103 m^3;
- the minimum point of the profile - 36 m;
- the maximum point of the profile - 51.2 m;
- the middle point of the profile - 43.6 m;
- temperature of transported oil - 40°C;
- temperature at the depth where the ipeline is buried - 5°C.

The investigation of the flow of oil through the pipeline was considered according to 2 options:

- It is assumed that the accident hole is at the level of the average height of the pipeline route. For the considered pipeline, this value is H_{ave}= 43.6 m as mentioned.
- In order to estimate the maximum spillage of oil, it is assumed that the accident hole occurs at the minimum point of the pipeline. As can be seen from picture 2, the 72nd section of the pipeline corresponds to the mentioned condition. In this case, the length of the pipeline between two crossing points is considered as the part under accident. That section is 1.1 km long and is located between section- 69 and 80.



1÷3- is the average height of profile (H_{ave}), pipeline (H_{pipe}) and oil discharge (H_{empty}) respectively

Figure 2: *Compressed profile of the pipeline route*

Considering that there are 17 intersection points at the average height (H_{ave}= 43.6) for the studied oil pipeline profile, and if the leakage point is located at the minimum point of the profile H_{min}= 39 m, then oil will flow into the accident hole from both sides. Since the intersection point divides the profile section into two parts, the oil flow area is located above the intersection point. At this time, the 2nd part will not be free of oil. The average length of the pipe section free of oil can be determined according to the following expression:

$$l_{ave} = 0{,}427 \cdot \frac{L}{n}, m \tag{3}$$

Here: L- the length of the pipeline, m; n- is the number of intersection points of the profile with the average height of the pipeline. If we consider the values of L and n in (3), we get:

$$l_{ave} = 0{,}427 \cdot \frac{8500}{17} = 213{,}5\ m$$

Fig. 3 shows the distribution of pressure during oil discharge in the oil pipeline section from the accident hole formed at the middle height of the profile in a non-pressurized mode. The discharge level corresponds to the vapor elasticity pressure of the oil.

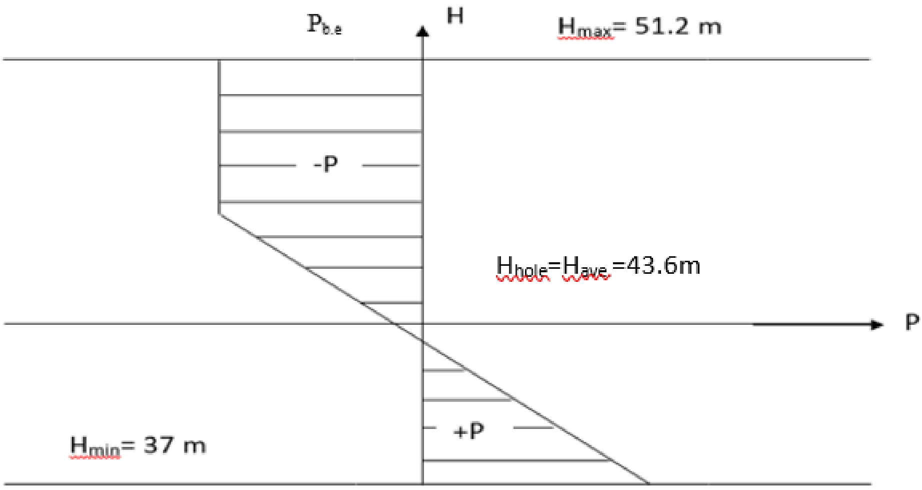


Figure 3: *Pressure distribution diagram in the damaged part of the oil pipeline*

According to the currently existing and above-mentioned methodical guidance, the volume of oil spilled during pipeline accidents is always assumed to be equal to the volume of the pipeline, regardless of the location of the damage. But as it turns out, even in the worst case, it is almost impossible to completely empty the pipeline. These are listed in table 1 in a comparative manner. As can be seen from Table 1, according to the existing methodical guidelines, the volume of accidental oil spills is increased by 39.8 and 7.6 times according to the mentioned scenarios (options).

It was also confirmed by analyzing the data of the Internet HSE AgensyLtd, Labor Protection, Industrial and Fire Safety, Warning of Emergency Events - Chronicle of Events and Accidents (2007-2008 years) [5] that the opinion about free flow of oil during the accident is not valid.

Table 1: *Assessment of accidental oil spills in pipelines under different scenarios*

Scenarios	The volume of oil pipeline, m^3	Pipeline discharge volume, m^3	Reconciliation of part share
According to methodological guidance [2].			
Probable Hypothetically	3103 3103	3103 3103	1 1
According to the proposed grapho-analytical method			
Probable Hypothetically	3103 3103	78 408	0,025 0,13

In those data, accidents related to oil spills from 8 different pipelines were investigated and systematized. Preliminary data characterizing oil spills occurring in oil pipelines of different diameters and systematized results are given in table 2.

Table 2: *Calculated results of the part of oil spilled from pipelines in free flow mode (based on accident statistics)*

0,15	9,1	10	176,6	64	1,0	2,1	7,0	0,0012	0,0396	3,96
1	12,8	10	7850	367	0,13	12,2	0,6	0,001	0,0001	0,01
1,2	26,0	10	11304	732	0,18	24,4	1,6	0,002	0,0001	0,01
0,7	43,0	10	3846,5	1246	0,90	41,5	1,5	0,004	0,0004	0,04
0,8	49,0	10	5024,0	1429	0,80	47,5	1,4	0,009	0,0003	0,03
0,6	51,5	10	1962,5	707	1,0	23,5	28,0	0,012	0,0143	1,43
1,2	126,0	10	11304	3744	0,91	124,7	1,3	0,011	0,0001	0,01
0,7	272,0	10	3846,5	2769	2,0	92,2	179,8	0,024	0,0467	4,67

Here,

D – Diameter of the oil pipeline, m;

V_o^s – the volume of oil spilled from the pipeline, m^3;

L_p^v – length of pipeline between valves ($L_p^v = 10km$) ;

V_p^v – volume of pipeline between valves, m^3 ;

$Q_o^{b.a}$- volumetric flow rate of oil before accident, m^3/hour;

v – flow velocity, m/s ;

V_o^p - volume of oil spilled under pressure (within 2 min)., m^3;

V_o^f – volume of oil spilled in free flow mode, m^3.

The volume of oil discharged in pressurized mode is determined based on the flow rate of oil flowing through the pipeline in 2 minutes, and the volume of oil flowing in free flow mode is determined based on the expression $V_o^f = V_o^s - V_o^p$.

As can be seen from the calculation results shown in Table 2, the volume of oil spilled in free flow mode does not exceed 3-5% of the volume of oil in the pipeline. The experience of long-term operation of main oil pipelines confirms the above.

III. Results

A grapho-analytical method was proposed for the evaluation of oil spills with free flow in pipelines. It was determined that even in the worst case, it is not possible to completely empty the oil pipeline. In the case of accidental spills, complete emptying of the pipeline in the free-flow mode is possible when holes are formed at all extreme points of the pipeline (at the maximum and minimum points of the profile) during the accident.

Abstract

"The idea of the proposed work is that the volume of an emergency discharge should be calculated based on the characteristics of the discharge event itself." There are some tools for this that are not used by developers of analysis methods. This refers to an automatic method of monitoring emissions using sensors up to an explosive gas concentration (EGC), automatic control of flow rates, pressure, visual control methods, by the sound of gas emissions, by the smell of a hazardous substance, etc. These methods, which can be calculated, are especially effective for partial depressurization of the block.

Keywords: emergency release, reliability, probability of depressurization, frequency, risk, technological equipment

I. Introduction

The level of reliability of oil field process equipment can also be seen in the forecast of the probability of complete depressurization of dangerous blocks, estimated by document [1] as the frequency of complete depressurization equal to 10^{-5} units/year. Let's consider the physics of the designated phenomenon and how it affects the reliability of equipment over time. Fig. 1 shows a graph characterizing the probability of failure of a technological unit due to its physical aging or wear. This graph is presented in LogP - LogT coordinates, where T is the operating time of the equipment, years, P is the probability of equipment failure.

II. Methods

To understand the essence of the analysis being performed, we note that the probability of failure (degree of wear) and the equipment reliability indicator add up to one. The higher the wear, the lower the reliability of the equipment. If we take as a boundary condition corresponding to the moment of block destruction the frequency of complete depressurization equal to 10^{-5} units/year. This means that complete depressurization of the block will occur once every 100,000 years. When analyzing the graph, you can find a variable value for the reliability indicator. If we take the probability of equipment failure at the level of 10^{-6} as an acceptable value, then it is found that at the initial stage and after 100 years of operation, the probability of failure is higher than the acceptable value. At the initial stage, the low reliability of equipment is explained by the presence of defects during its production at the manufacturing plant, the appearance of additional defects during its transportation to the construction site and during installation as part of the construction project. During operation, equipment wears out, accompanied by a decrease in residual life. Wear is expressed by a change in the thickness of power elements due to corrosion, the appearance of microcracks in critical equipment components caused by cyclic loads, changes in the structure of the metal as a result of aging, etc. The ability of equipment to completely depressurize is determined by the degree of its wear. The standard operating life of machines and devices does not exceed 10–15 years. As follows from the analysis of the reliability graph, the probability of complete depressurization of equipment within the established resource is negligible, therefore we consider it unacceptable to use complete depressurization as the main scenario for the development of an accident.

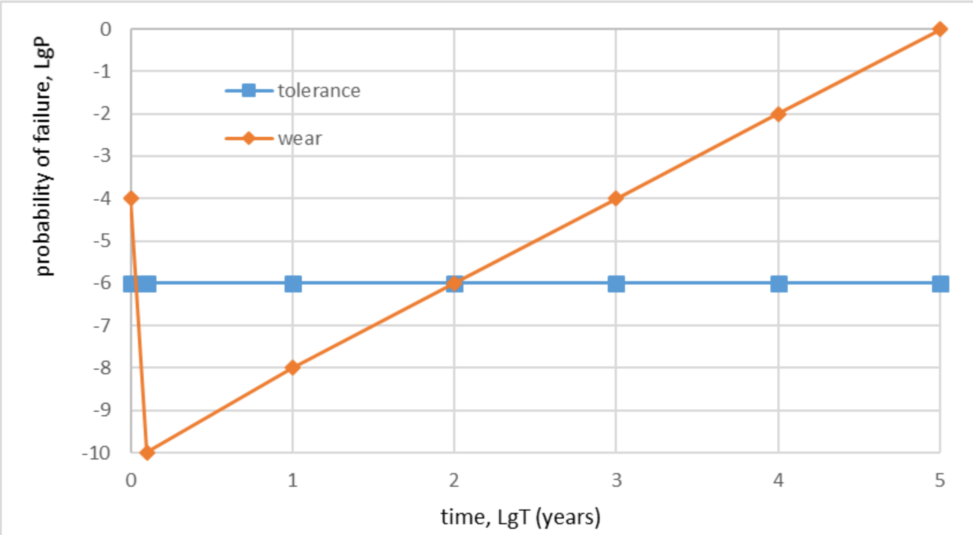

Fig.1: *Depenedence of equipment wear on time*

Accident statistics were most fully presented in RD 03-357-00 [1], where the following indicators can be found in Table 1: probability of depressurization of a process pipeline with a length of no more than 30 m $5x10^{-3}$ per 1 km of pipeline per year; probability of depressurization of the main pipeline (1-3) x 10^{-4} per 1 km of pipeline per year; probability of failure of machinery (pump or compressor) 3 x 10^{-3} per 1 km per year; the probability of complete destruction of the reservoir is 10^{-5} per year; the probability of partial depressurization of the tank is 10^{-4} per year.

Table 1: *Probability of depressurization of process equipment*

The probability of depressurization of a process pipeline with a length of no more than 30 m.	$5x10^{-3}$ per 1 km of pipeline per year
Probability of depressurization of the main pipeline	(1-3) x 10^{-4} per 1 km of pipelines per year
Possibility of failure of machinery (pump or compressor)	$3x10^{-3}$ per 1 km per year
Probability of complete tank destruction	10^{-5} per year
Probability of partial depressurization of the tank	10^{-4} per year
Possibility of rupture of connecting hoses during draining/filling of railway and road tanks	10^{-3} per refill or 10^{-2} per hose

As a base, we have to use the data presented in the table, which in the original source is called "Generalized statistical data for assessing the frequency of equipment failures." In particular, the value of partial block failure is presented here as the "probability of failure (incident)" with the dimension "per year". From the theory of probability, from the instructions of GOST R 50779.10-

2000 [2], it follows that the probability of a random event is a dimensionless quantity. The "frequency" or "probability" of partial block failure is 10^{-4}. With the release of the Methodology [3], a database on depressurization of process equipment, tanks and pipelines appeared. In appendix 1 to the specified Methodology, tables appeared indicating the frequency of complete and partial depressurization for certain types of equipment and process pipelines. The frequency of partial depressurization is presented in tables for different sizes of emergency opening in the range from 5 to 100 mm for equipment and from 12.5 to 100 mm for pipelines. In this case, each size of the emergency hole is assigned a certain frequency of system depressurization. According to the idea of this document, the volume of release should be determined depending on the size of the emergency opening. What to do next with the resulting emission volumes? The volume of release is determined not by the size of the emergency opening during partial depressurization of the system, but by the method of monitoring the tightness of the system. Partial depressurization is a dynamic process. It starts with a small omission of product and only in the absence of control will it progress over time. For partial depressurization of devices operating under pressure, 5 depressurization stages have been installed with emergency opening sizes of 5, 12.5, 25, 50 and 100 mm. As a result of lengthy calculations, it is possible to determine the volume of oil or gas release for each hole size[4]. Then, for all emission volumes, perform calculations of affected areas. What to do next with this data array? Our approach to solving this problem is as follows: The volume of emergency release in the event of partial depressurization of an apparatus or pipeline is determined not by the size of the emergency hole, but by the method of monitoring the tightness of the system. The volume of emergency release at on-site facilities equipped with an automatic gas control system is determined by the sensitivity of the control system. At linear structures and well pads, where there are no maintenance personnel, control of the system tightness is carried out by personnel on duty (inspectors of linear structures, mobile crew at well pads) at established intervals. The size of the oil slick formed on the surface of the earth is taken as an indicator of depressurization. In this regard, as a database on the frequency of partial depressurization (FPD), we take the total frequency presented in the tables of the Methodology [3,5,6]. As a result of summing the frequencies of partial depressurization, accident statistics are presented in Tables 2 and 3.

Table 2: *Frequency of depressurization of equipment and tanks*

Name of technical device	Dimension	Depressurization frequency	
		Partial	Complete
Devices under excess pressure > 0.07 MPa	pcs/year	$6{,}2 \times 10^{-5}$	3×10^{-7}
Pumps	pcs/year	$5{,}62 \times 10^{-3}$	1×10^{-4}
Compressors	pcs/year	$1{,}28 \times 10^{-2}$	1×10^{-4}
Tanks and reservoirs under pressure < 0.07 MPa	pcs/year	1×10^{-4}	5×10^{-6}

Table 3: *Frequency of depressurization of process pipelines*

Pipeline diameter, mm	Specific failure rate, pcs/km/year	
	Partial depressurization (PD)	Complete depressurization (CD)
50	8×10^{-3}	$1{,}6 \times 10^{-3}$
80	6×10^{-3}	4×10^{-4}
100	$4{,}5 \times 10^{-3}$	$1{,}6 \times 10^{-4}$
150	3×10^{-3}	$2{,}6 \times 10^{-5}$
200	$2{,}4 \times 10^{-3}$	$1{,}8 \times 10^{-5}$
250	$1{,}9 \times 10^{-3}$	$1{,}6 \times 10^{-5}$
300	$1{,}7 \times 10^{-3}$	$1{,}4 \times 10^{-5}$
400	$1{,}4 \times 10^{-3}$	1×10^{-5}

500	$1x10^{-3}$	$8x10^{-6}$
600	$8x10^{-4}$	$6,5x10^{-6}$
700	$7x10^{-4}$	$5,5x10^{-6}$

Calculation of the probability of leakage of flammable substances P1

Assuming that the start of a typical most probable accident is the partial destruction of a dangerous unit, the probability of a leak is determined by the product of the frequency of leaks of this element and the duration of the leak. $P_i = Nt$, where P_i is the probability of leakage of a hazardous substance; N – leakage frequency of the i-th element; t is the duration of the leak.

Calculation of emergency depressurization frequency N

The frequency of emergency depressurization is determined based on statistical data on the frequency of depressurization of individual units of the installation. The frequency of emergency depressurization can be determined for one unit (as a statistical indicator of the failure rate), for a group of units included in 1 technological installation (as the sum of the depressurization frequencies of the units included in the installation), for a complex of installations (as the sum of the depressurization frequencies of technological installations) and etc.

Determining the amount of hazardous substance involved in the accident

Data on the amount of hazardous substances released into the environment are necessary to solve the following problems:

- To determine the damage associated with the loss of valuable hydrocarbon raw materials;
- To determine the amount of compensation for damage to the environment;
- To determine the areas affected by personnel and the population during fires of flammable liquid spills;
- To determine the cost of restoring an object after an accident;
- To generate risk indicators, the frequency and probability of explosions and fires, the probability of injury to personnel and the population, and determine the locations of possible injury;
- To develop recommendations to reduce risk

III. Results

1. The use of the term "probability" with the dimension of frequency is unacceptable, since this follows from the theory of probability, which has no dimension.
2. The volume of emergency release in the event of partial depressurization of the system is determined not by the size of the emergency hole, but by the method of monitoring its tightness.

IV. Discussion

Emission potential

The consequences of accidents associated with the release of a hazardous substance into the environment determined by the energy potential, which can be realized in an unfavorable scenario. For fire and explosion hazardous industries that use flammable substances (liquids and gases), the main scenario of the emergency process is the oxidation of these substances with atmospheric oxygen, which leads to a fire or explosion. The consequences of such an accident determined by the magnitude of the energy potential of the flammable substance that can take part in the oxidation reaction. Let's consider an algorithm for calculating the amount of substances released for oil field facilities. Based on the nature of production, fisheries can be divided into the following groups:

- On-site facilities with the constant presence of maintenance personnel;
- On-site facilities with staff visits once a day;
- Linear structures controlled by a lineman once a day.

At the location of the release, hazardous objects can be above-ground or underground. This indicator has a significant impact on the volume of flammable substances involved in creating hazards. Based on the volume of release, accidents are divided into 2 groups: with partial depressurization of the unit and with complete destruction of the unit. Combustible substances can be in liquid or gaseous state. Liquid substances can accumulate for a long time on the surface of the earth. Gaseous substances create a cloud of gas-air mixture of certain sizes. Taking into account dispersion in the atmosphere, the size of the cloud depends on the consumption of flammable substances in the emission. With a long-term release, the potential stabilizes at a certain level, after which all additionally released gas is dissipated in the atmosphere. Methods for monitoring the tightness of a technological system can be divided into automatic and visual. Automatic methods include methods for monitoring technological parameters (pressure, level, flow), by changing which one can indirectly determine the degree of depressurization of the technological unit. The specified parameters make it possible to determine the possibility and degree of depressurization of a dangerous unit. In addition, automatic methods include direct methods for monitoring the presence of flammable substances in the environment, carried out using flammable gas detection systems using sensors up to explosive concentration (EVC), a sensor cable that reacts to the presence of oil and its products. The volume of methane emission that initiates the sensors, with their average distance from the emission site of 11.2 m, is 22 m^3.

Abstract

The experience of drilling oil and gas wells shows that one of the most common complications that occur in the drilling process is the stuck pipe. Scientists and drilling experts explain and prove the occurrence of such cases for various reasons. Indeed, these reasons are very different. Taking into account the new physical model of multiphase flow and rheological properties, the issue of evaluation of the mechanical particles (debris) as a result of the dislocation (movement) along the axis of the cylindrical flow because of the interaction of the phases in the drilling fluid as a factor causing compression and stuck pipe was considered in the article.

Keywords: drilling fluids, pressure gradient, visco-plastic, shear stress, stuck pipe

I. Introduction

As it is known, oil and gas extraction, gathering, transportation to processing sites, separation, as well as oil, gas, formation water and mechanical particle cleaning processes are based on multiphase technologies.

It is known that the process of drilling oil and gas wells is carried out with the participation of drilling fluid, and this fluid performs several important functions. Thus, during drilling, it constantly circulates and brings the drilled rock fragments to the surface, which is one of its main functions. At this time, there are horizontal, up-bottom and bottom-up movements of the drilling fluid in laminar mode. Based on a large number of rheological studies, it was determined that drilling fluids are mainly described by a viscoplastic (pseudoplastic) rheological model [1÷4].

The movement of the drilling fluid, which has visco-plastic properties, settled in the pipe was studied by us.

It is known that the following dependence is used for the rheological description of visco-plastic fluids (Shvedov-Bingham model):

$$\tau = \tau_0 + \mu \frac{dv}{dr} \tag{1}$$

μ- plastic viscosity;

v- flow velocity.

It is typical for visco-plastic flows that they have the initial shear stress τ_0 [4, 5, 6]. At values greater than this tension, the structure of the liquid begins to disintegrate. After a certain critical velocity, the dependence $\tau = f(\gamma')$ turns into a linear dependence, and the motion of the fluid is characterized by plastic viscosity, being the motion of a Newtonian fluid ($\mu = tg\beta$). The dynamic shear stress – yield point (τ_d) is determined by extending the linear part of the dependence until it intersects the ordinate axis. It should also be noted that yield point cannot be determined experimentally.Unlike the dynamic viscosity coefficient, the plastic (structural) viscosity coefficient (μ) does not have a constant value for most fluids. As a rule, for non-Newtonian fluids, the concept of effective viscosity at a certain shear rate is used. This viscosity is calculated based on the tangent of the slope angle as a function of the shear rate ($\mu = tg\alpha$). The analysis shows that most of the fluids with visco-plastic properties show a decrease in viscosity with increasing shear rate.

The shear stress distribution along the cross-section and the yield point can be determined according to the following known expressions:

$$\tau = \frac{\Delta P * r}{2l}; \qquad \tau_0 = \frac{\Delta P * r_0}{2l} \qquad (2)$$

ΔP is the pressure difference.

The tangential stress on the pipe wall (when r=R) takes a maximum value..

$$\tau = \tau_{max} = \frac{\Delta P * R}{2l}$$

τ = 0 when r = 0 on the pipe axis. $\tau = \tau_0$ and $dv/dr = 0$ on a cylindrical surface with radius $r = r_0$ from the pipe axis. In the interval $0 \le r \le r_0$, the velocity of the flow remains constant, in other words, the cylindrical part with the radius r_0 moves like a solid body and is considered the core of this flow. The radius of the core is found from the following equation based on the condition $\tau = \tau_0$:

$$r_0 = \frac{2l * \tau_0}{\Delta P}$$

According to the last condition, $\tau > \tau_0$ should be on the inner surface of the tube for the fluid to move. When $r = R$, the initial pressure difference (ΔP_0) corresponding to the stationary state of the fluid ($\tau = \tau_0$) will be as follows:

$$\Delta P_0 = \frac{2l * \tau_0}{R}$$

That is, it is important to have the condition $\Delta P > \Delta P_0$ for the fluid to move in the pipe.

Let's examine how the gradient-velocity field changes during laminar flow of non-Newtonian drilling fluid. For this purpose, let's examine how the velocity and pressure gradient change along the cross-section of the pipe.

It is known that the change of the pressure gradient along the cross-section can be determined by the following mathematical equation [5,6]:

$$\frac{dP}{dr} = \rho v \frac{dv}{dr} \qquad (3)$$

Here ρ- density of drilling fluid.

Let's assume that the change in velocity (v) during the flow of the drilling fluid in the pipe occurs with the following expression:

$$v = Ar^2 + Br + C \qquad (4)$$

Let us use the following boundary conditions to determine the coefficients A, B and C included in the trinomial (4):

1. When $r = R$, velocity $v = 0$ at the pipe wall is assumed .

$$Ar^2 + Br + C = 0$$

2. $\frac{dv}{dr} = 0$ when $r = r_0$,

$$\frac{dv}{dr}_{r=r_0} = 2Ar_0 + B$$

3.

$$\tau_{max} = \mu \frac{dv}{dr}_{r=R} + \tau_0$$

$$\tau_{max} = \frac{\Delta P * r}{2l}; \qquad \tau_0 = \frac{\Delta P * r_0}{2l}$$

Using the mentioned conditions above, we get the following expressions for determining the coefficients A, B, C included in equation (4):

$$\left.\begin{aligned} A &= -\frac{\Delta P}{4\mu l} \\ B &= \frac{\Delta P r_0}{4\mu l} \\ C &= \frac{\Delta P R^2}{4\mu} - \frac{\Delta P r_0}{2\mu l} \end{aligned}\right\} \qquad (5)$$

From the last expressions, taking into account the coefficients A, B, C, the following expression can be written for the determination of the distribution of the velocity along the cross-section of the pipe:

$$v = \frac{\Delta P}{4\mu l}(R^2 - r^2) - \frac{\tau_0}{\mu}(R - r) \tag{6}$$

According to expression (6), the change of the velocity gradient along the cross-section is as follows:

$$\frac{dv}{dr} = \frac{\Delta P(r_0 - r)}{2\mu l} \tag{7}$$

If we consider the expressions characterizing the distribution of velocity and velocity gradient (6) and (7) and the expression of τ_0 in equation (3), we get the following expression reflecting the distribution of the pressure gradient along the cross-section:

$$\frac{dP}{dr} = \frac{\rho \Delta P^2}{4\mu^2 l^2}(r - r_0)[2r_0(R - r) - (R^2 - r^2)] \tag{8}$$

Considering that the expression (6) reflecting the cross-sectional velocity distribution of visco-plastic fluids during laminar flow is true only in the interval $r_0 \le r \le R$, then when $r = r_c$, as can be seen from the expression (8), the pressure gradient becomes 0 $\frac{\Delta P}{\Delta r} = 0$. By the same rule, when r = R, that is, the pressure gradient on the pipe wall is equal to 0 ($\frac{\Delta P}{\Delta r} = 0$) and in the center of the tube (when r = 0) $\frac{dP}{dr} = \frac{\rho(R-2r_0)\tau_{max}\tau_0}{\mu^2}$.

The maximum value of the pressure gradient along the cross-section can be determined by deriving the expression (8). So, if we take the derivative of that expression with respect to r and make it equal to zero, we get the following quadratic equation:

$$3r^2 - 6r_0 r + (2r_0 R - R^2 + 2{r_0}^2) = 0$$

Following roots are obtained from the solution of the last equation with respect to r:

$$r_1 = r_0 + \frac{\sqrt{3}}{3}(R - r_0)$$

$$r_2 = r_0 - \frac{\sqrt{3}}{3}(R - r_0)$$

As you can see, although the second root satisfies the equation because $r_2 < r_0$ is obtained, it contradicts the condition $r \ge r_0$ mentioned above. Therefore, the pressure gradient dP/dr will have a maximum value at $r^* = r_0 + \frac{\sqrt{3}}{3}(R - r_0)$. This value will be as follows:

$$\frac{dP}{dr}_{max} = \frac{\sqrt{3}\rho(R - r_0)(\tau_{max} - \tau_0)^2}{3\mu^2}$$

The variation of flow parameters (velocity, tangential stress, velocity gradient and pressure gradient) for visco-plastic fluids is shown in Fig. 1.

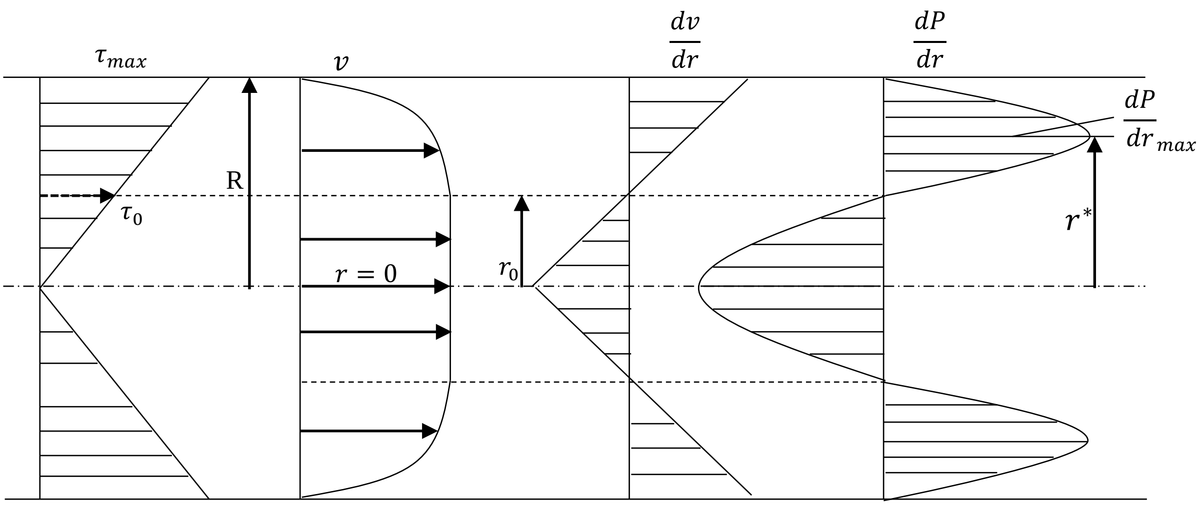

Figure 1: *Cross-sectional distribution of flow parameters of visco-plastic drilling fluid*

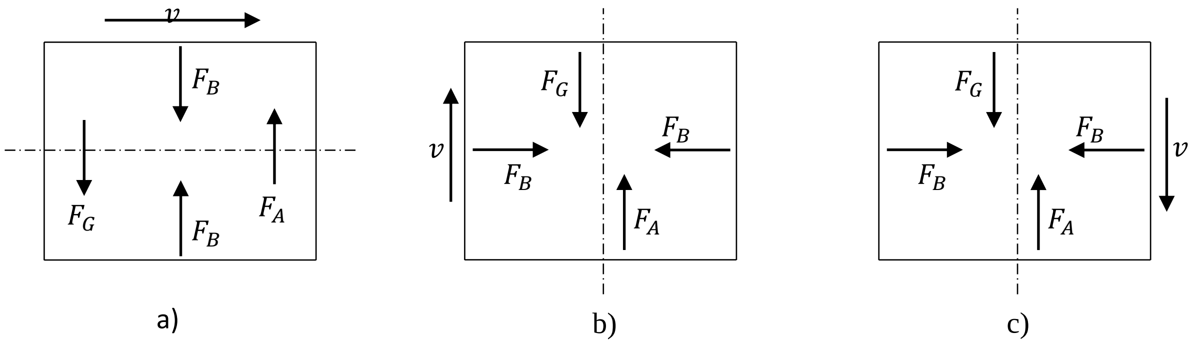
Studies show that the structure of multiphase flows (gas-liquid, oil-water-gas, oil-gas-mechanical particles, drilling fluids, etc.) is highly dependent on the orientation and direction of movement of the channel (pipe). So, during the movement of these flows in the vertical pipe from top to bottom and vice versa from bottom to top, as well as in horizontal direction, their characteristics differ significantly from each other. Although there is currently a considerable amount of scientific research work on horizontal and bottom-top vertical flows, top-bottom flow forms have been limited studied .

The results of scientific research conducted in recent years have shown that there is mutual influence of phases in multiphase cylindrical flows regardless of the direction [5÷8]. As the gradient-velocity field is formed not only along the length but also along the cross-section of the flow according to the law of conservation of energy, the continious phase is able to transport dispersed phase particles along the axis of the flow, in its center. Due to the Bernoulli force, which is directed from the edges of the cylindrical flow towards the center, those particles (mechanical, gas, water, etc.) very easily move in the core of the continious phase, being directed to the axis of the flow.

It is known that during such flows mainly gravity, Archimedes, and Bernoulli forces (if we do not consider friction and inertia forces) are active forces, which cause sedimentation and migration phenomena. It is clear that although the direction of these forces is known, their effect will be different depending on the direction of the multiphase flow. So, in vertical downward and upward flows, Archimedean and gravitational forces will be opposite to each other, and Bernoulli's force will be perpendicular to them. In the case of horizontal flows, although the direction of all three forces is perpendicular to the flow, the Bernoulli force will be perpendicular to the axis of the flow from the edges, and the Archimedean and gravitational forces will be opposite to each other. Schematically, the directions of these forces in different directional flows are shown in figure 2.



a-horizontal, b- bottom to top, c-top to bottom

Figure 2: *Direction of active forces in multiphase flows with different directions*

F_B – Bernoulli force, F_A – Archimedes force, F_G – Gravitational force

Thus, the cross-sectional transfer of matter and energy in multiphase flows does not occur only due to turbulent diffusion. This process is also caused by the directed movement of the medium itself. Such transfer phenomena, which are characteristic of multiphase flows and multicomponent drilling fluid, occur due to the Bernoulli force, which causes the interaction of phases in both horizontal and gravity flows[4, 7]:

$$F_B = 0.167\pi d^3 \frac{dP}{dr} \quad (9)$$

Here d - the diameter of the dispersed phase particle, the volume of the particle (gas bubble, mechanical particle, scrap, etc.) with a diameter d of $0.167\pi d^3$;

dP/dr - is the pressure gradient across the flow cross-section.

The transfer movement of the flow along the cross-section occurs under the influence of the pressure gradient along the length (height), against the background of the movement of the medium. Turbulence of the flow also increases with the increase of the average flow rate, because the pressure gradient along the cross-section increases more intensively with the increase of the velocity.

If we consider the expression that reflects the change of expressions of pressure gradient, v and dv/dr, in equation (9) we get;

$$F_B = 0.167\pi d^3(\rho_{m.h} - \rho_m)g \tag{10}$$

As can be seen from the last statement, the Bernoulli force directed from the pipe wall to the center of the flow in the cylindrical flow increases significantly as the density difference of the mechanical particles and fluid (drilling fluid) and the diameter of the mechanical cuttings increase.

As can be seen from the last expression, the migration of the dispersed phase to the center of the flow is inevitable despite the high degree of dispersion even in the small diameters of the rock fragments. Therefore, due to intensive migration (transportation) of drilled rock particles to the center of the flow due to the effect of the Bernoulli force caused by the variable pressure gradient, it can greatly increase the local resistance caused by friction and cause the stuck pipe.

II. Conclusions

– Based on the physical model of multiphase cylindrical flows, the regularity of the formation of the velocity-gradient field during its movement in the pipe, taking into account the visco-plastic properties of the drilling fluid, has been shown.

– It has been shown that one of the possible causes of stuck pipe during drilling of oil and gas wells is due to the compression of the tool as a result of the dislocation of mechanical particles and rock fragments in the direction of the flow axis due to the Bernoulli force formed by the velocity-gradient field.

MULTIMEDIA SUPPORT SYSTEM FOR AEROSPACE MONITORING OF EMERGENCY SITUATION BASED ON AI TECHNOLOGIES

Nazif Sattarov
•
Azerbaijan National Aerospace Agency
nsattarov@gmail.com

Abstract

Technological development, digitalization, cybersecurity, the use of artificial intelligence, all these areas are becoming part of the everyday life of society. Along with the task related to renewable energy, the republic is making its contribution to solving climate change issues. This year, the international conference COP29 will be held in Azerbaijan under the auspices of the UN Framework Convention on Climate Change. In this regard, the attention of the international community will be directed to our country, namely to activities in the field of environmental protection and climate change. Based on this, it is necessary to introduce new solutions and innovations that will help reduce the negative consequences of climate change. One of the important problems is global warming. It leads to disruption of the natural ecosystem, including the occurrence of hazardous natural phenomena and destructive natural disasters. Forecasting the occurrence and development of natural and man-made phenomena on Earth is of great relevance. Direct damage from all types of emergency events amounts to a huge amount. Preventing emergency situations (ES) based on monitoring their precursors is more economically profitable than responding to the consequences of emergencies. Thus, one of the main tasks of disaster risk management is monitoring and forecasting emergencies. The noted consists in constant monitoring of processes occurring in nature and the technosphere with the aim of scientific prediction of possible dangerous phenomena. The forecasting system includes information about the forecast object, which reveals its behavior in the past and present, as well as the patterns of this behavior. Information about these precursors should be sent to the monitoring and forecasting center using monitoring systems. Here, appropriate predictions are made based on heuristic and mathematical methods. According to the area of occurrence, emergencies are divided into natural and man-made ones. On the base of the above-mentioned facts, this paper is aimed of discussing several important features of multimedia support system for aerospace monitoring of emergency situation on the Caspian Sea using technologies AI.

Keywords: multimedia, support system, aerospace monitoring, emergency situation, AI technologies

I. Introduction

The major environmental issues in the 21st century include: climate change, freshwater scarcity, deforestation and desertification, freshwater and marine pollution, loss of biodiversity, air pollution, soil and natural resource depletion [2]. The environment is considered favorable if its condition meets the criteria and standards established by environmental legislation regarding its cleanliness (non-pollution), resource intensity, environmental sustainability, species diversity and aesthetic richness. The Republic of Azerbaijan is a party to a number of international conventions in the field of environmental protection, including the Convention on Environmental Impact Assessment (EIA) in a Transboundary Context (Espoo Convention) [1,4]. At its core, the Espoo Convention is a means to help Parties (states) cooperate, jointly discuss problems, exchange opinions and experiences. This Convention represents a set of opportunities for countries in the Economic Commission for Europe region, but at the same time the way they implement them needs to be improved. The most important task at the present stage is to know the boundaries of

HOMEOSTASIS, that is, those critical values of the parameters of the biosphere, beyond which the unpredictable development and destruction of the biosphere begins. Information in the field of environmental protection includes the state of the environment, impacts on the environment, and regulation of environmental quality. An ecosystem of a certain type is preserved only with certain combinations of ecological components. Otherwise, if the balance of eco-components is disturbed, irreversible processes will be observed (classic example: degradation of the Aral Sea) [5]. The most significant changes in ecosystems are caused by significant reasons (accidents on oil pipelines, fires, soil degradation, deforestation, emissions of pollutants into the atmosphere, water bodies and seas, etc.). Within the framework of the scientific and technical work "Development of a multimedia model for aerospace monitoring of emergency situations based on expert systems technology", carried out at the Institute for Space Research of Natural Resources ANASA, three groups of issues are considered: characteristics of the Caspian Sea, oil production and transportation, aspects of emergency situations at sea. Remote research is carried out with the aim of confirming or rejecting a particular scientific hypothesis. Monitoring as a system includes a subsystem for collecting, accumulating and transmitting information, as well as a subsystem for processing, modeling, analyzing and forecasting data. At the monitoring and forecasting center, appropriate predictions are made based on heuristic and mathematical methods [6,9].

Promptly obtaining information about the coverage area, level and quality of the event in each geographic point of the emergency area is one of the main factors that can reduce the tension of the situation in the region. In this regard, the features of multimedia technologies are: the transformation of traditional maps into multimedia ones. Here, along with maps and texts for them, audiovisual information is important: pictures, animation, sound, 3d graphics; a visual representation of the process under study (its phase), for example, in the form of an animated film. Based on this, the "revival" of the components of the IF - THEN heuristics, in the form of static snapshots (pictures), was demonstrated for the first time. The objects of monitoring in this work are aspects of emergency situations. The purpose of monitoring is not a passive statement of facts. It should also include modeling of the processes under study, generalization of accumulated world experience in assessing and forecasting natural and man-made hazards, development of multimedia data banks on various aspects of emergency situations, etc.

II. Methods

A cognitive multimedia monitoring model (CMMM) is proposed in the form of a set of interconnected elements

$$B=B_k, \qquad B_k=R_1^k \cup R_2^k \cup R_3^k \cup \ldots \cup R_{l-1}^k \cup R_l^k = \bigcup_{j=1}^{l} R_j^k$$

The model characterizes the various phases of the study, where: R_j is the set of elements of the j-th group model; here $K=m,n,p$: m – number of elements, $m=\overline{1,M}$; l - number of groups, $l=\overline{1,L}$; n – form of representation of semantic information, $n=\overline{1,N}$ (with $N=4$ we have t, S, g *and* C – forms, where t – text form, S – audio form, g – dynamic (dynamic video images) form, C – graphic (static images: maps, aerospace images, graphs, diagrams, etc.) form; p – type of observations (*2d or 3d*).

CMMM from the position of a researcher represents a certain task, which has conditions, a goal and means of achieving it. Solving a problem is a process of dialogue interaction between a researcher and a complex that has access to the Internet according to a pre-formed strategy. During the dialogue, the current state of the object model is displayed. The course of the process is assessed according to an established criterion (for example, extremes: signal/noise ratio, time to reach the goal, etc.).

The CMMM identifies three functional components: a multimedia model of the subject area (technological process), phases of the technological process, interactive interaction of the researcher with the complex and dialogue with experts on the Internet.

CMMM elements are associated with specific indicators of technical means (for example, on-board sensor systems) [7] ; data from simulation modeling, mobile environmental laboratories.

A multimedia model of a subject area is a set of audiovisual forms of the phases of a technological process and the laws of change in their content. Process phases, i.e. multimedia images of source data are relationships and conditions that define the task for studying a given situation [8]. The multimedia model is designed to display the parameters and states of various research objects, i.e. information models (IM).

III Results

Thus, the developed cognitive multimedia monitoring model is a set of interconnected static and dynamic information models of objects (processes, phenomena) and background images.

Forms of representation of semantic information. Based on the theory of semantic networks, homogeneous and complex forms of representation of semantic information are distinguished. The set of homogeneous forms is determined by the expression

$$N_1 = \{t, S, g, C\}$$

The complex form of representation of semantic information consists of several homogeneous forms, namely: text and auditory, text and graphic, graphic and visual, etc. In the general case, many options for complex forms of representing semantic information are determined analytically. To do this, using the operation of direct product of sets, from the elements of set N1 they form set N2, which contain double elements

$$N_2 = N_1 \cdot N_1 = \{(t,t), (t,S), (t,g), (t,C), (S,t), (S,S), (S,g), (S,C), \\ (g,t), (g,S), (g,g), (g,C), (C,t), (C,S), (C,g), (C,C)\}.$$

As a result, the resulting expression defines a list of complex forms of representation of semantic information that simultaneously combine two homogeneous forms (16 double elements). These complex forms are binary forms of expressing semantic information.

In order to obtain further diversity, ternary forms are used, which simultaneously combine three homogeneous forms

$$N_3 = N_1 \cdot N_1 \cdot N_1 = \{(t,t,t), (t,S,t), (t,g,t), (t,C,t), \ldots, (S,S,S), \ldots, (S,C,t), \ldots, (g,g,g), \ldots,\}$$

As a result, 64 ternary elements are obtained. Thus, it is possible to obtain complexes containing four, five, six or more simultaneously combined forms of representation of semantic information.

IV Discussion

Current emergency issues [3] are important for both scientific and practical activities. As part of our research, we have identified and selected the main aspects of emergency situations in the Caspian Sea.

The Fig.1: shows a general scheme of emergency situation at sea.

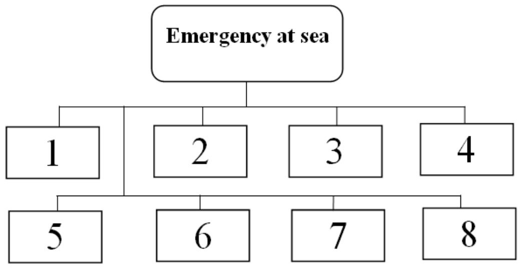

Figure 1: *General scheme of emergency situation at sea*
Legend: 1 - Oil spills; 2 – Fire on a fixed platform; 3 – Volcanic activity; 4 – Ice; 5 – Storm; 6 – Oil transportation problem; 7 – Sea level change; 8 - Earthquake

The selected material is the basis for the subsequent creation of multimedia data banks for a multimedia support system for aerospace monitoring.

The use of complex forms to express semantic information is of great practical importance in solving various remote sensing problems, since the degree of knowledge of an object increases with the simultaneous (complementary) representation of its aspects by multiple forms.

Azerbaijan is both an oil-producing country and a transit territory for the transportation of petroleum products, which creates an additional burden on ecosystems. The main stages of oil use are considered: 1. Exploration of oil fields. 2. Oil production. 3. Oil transport. 4. Refining and petrochemicals. 5. Use of petroleum products. 6. Waste disposal. All of these stages are associated with environmental pollution. In particular, when transporting oil, dangers are associated with transportation (by sea, land) and with pipeline rupture.

At the same time, the anthropogenic load on the marine ecosystem, coastal zone ecosystems, and ecosystems along the pipeline route increases. As a result, an extensive set of possible problematic situations and contradictions between human intentions and the capabilities of nature emerges. The Caspian region can be represented as a set of interconnected ecosystems.

Knowledge of the patterns of ecosystem behavior and factors that influence ecological balance is important.

Characteristics of the Caspian Sea.

Sea coordinates:
1. North latitude: $36^0 33^/ – 47^0\ 07^/$ N
East longitude: $45^0\ 43^/ – 54^0\ 03^/$ E
2. Its length ---------- 1200 km
3. Width -------------------310 km (average)
435 km (max)
4. Depth --------- ----208 m (average)
1025 m (max)
5. Division of the Caspian
1. -- north
2. – average
3. – south
6. The area of the Caspian Sea --------------- 3.5 million km^2
7. The area of the sea water area ----- 386.4 thousand km^2

The Fig.2: shows the general scheme of oil transportation.

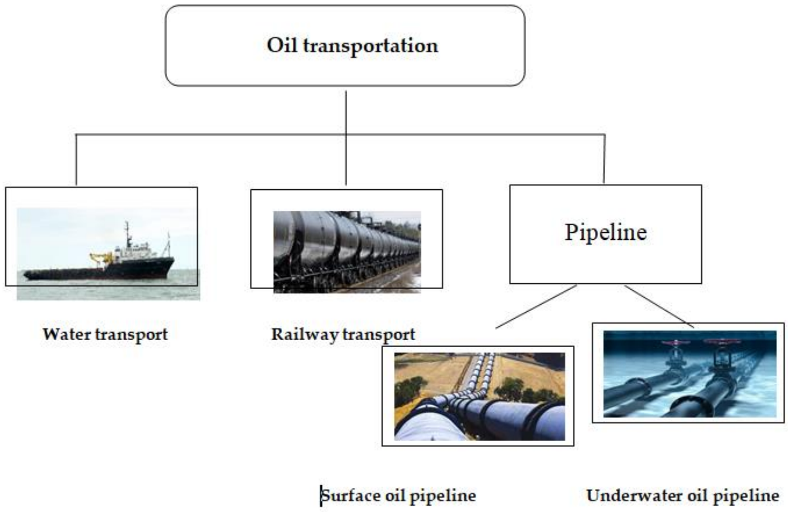

Figure 2: *General scheme of oil transportation*

We analyzed incidents of aspects of emergency situations in the Caspian Sea: 1. Mercury tanker accident; 2. Freezing (covering with ice) of the northern part of the sea. A broken block of ice in the area of the Neft Dashlari field; 3. Fire on the Guneshli oil platform; 4. Storm at sea in the area of stationary platforms; 5. Volcano activity at sea; 6. The problem of oil transport at sea; 7. Fluctuations in sea level and the Kura River; 8. Oil stains on the surface of the sea.

Along with incidents of aspects of emergency situations in the Caspian Sea, we separately examined incidents in other regions of the world:

1. The problem of a Japanese oil tanker that ran aground near the island of Mauritius;
2. Fire on the fixed oil platform "Deepwater" in the Gulf of Mexico.

Development of informative heuristics based on IF-THEN constructions. Visual forms of heuristics.

Heuristics 1.

1. IF a fire breaks out on a large oil platform and the platform collapses,
2. THEN there is a high probability that an oil spill will spread to the surface of the sea.

Figure 3: *A visual form of heuristics 1(IF component)*

Heuristics 2.

1. IF an oil pipeline accident occurs,
2. THEN the probability of an oil spill spreading is high.

Figure 4: *A visual form of heuristics 2 (THEN component)*

Let's consider a fragment of a visual database for generating heuristics for the problem under study.

The Fig.5: shows a block diagram of the animation algorithm for an oil slick leaking from an underwater oil pipeline (phase 1) and the formation of an oil slick on the sea surface (Phase 2).

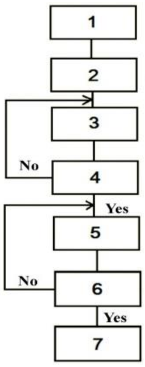

Figure 5: *Block - diagram of the animation algorithm for an oil slick leaking from an underwater oil pipeline (phase 1) and the formation of an oil slick on the sea surface (phase 2)*
Legend: 1. beginning; 2. animation; 3,4. phase 1; 5,6. phase 2; 7. end

The Fig.6 shows an animation diagram of an oil leak from an undersea pipeline.

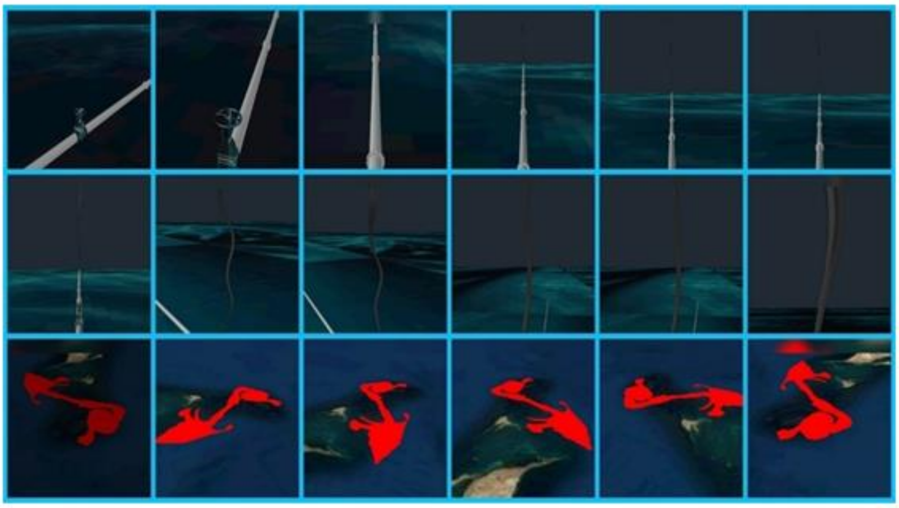

Figure 6: *An animated diagram of an oil spill from an undersea oil pipeline*

Abstract

Artificial Intelligence (AI) has emerged as a transformative tool in forecasting and managing technical risks across various industries. By leveraging machine learning algorithms, data analytics, and predictive modeling, AI enables the identification, assessment, and mitigation of potential technical failures with unprecedented accuracy and efficiency. This paper explores the role of AI in enhancing risk management practices, particularly in sectors such as finance, manufacturing, energy, and cybersecurity. AI's ability to process vast amounts of data in real-time allows for early detection of anomalies, prediction of equipment malfunctions, and optimization of maintenance schedules. Additionally, AI-driven risk management systems can adapt to evolving risk landscapes, improving decision-making and reducing operational costs. Despite its potential, challenges such as data quality, algorithmic bias, and integration with existing risk management frameworks remain. The study concludes that while AI offers substantial benefits in technical risk forecasting and management, it must be deployed with careful consideration of these challenges to maximize its effectiveness.

Keywords: anomaly detection, equipment failure prediction, real-time data processing, risk mitigation, operational efficiency

I. Introduction

In today's rapidly evolving technological landscape, managing technical risks has become a critical concern for organizations across various industries. The increasing complexity of systems, coupled with the growing reliance on digital infrastructure, has heightened the potential for failures that can lead to significant operational disruptions, financial losses, and reputational damage. Traditional methods of risk management, while effective to an extent, often struggle to keep pace with the dynamic nature of these challenges. This has created a demand for more advanced, data-driven approaches capable of predicting and mitigating risks before they materialize.

Artificial Intelligence (AI) has emerged as a powerful solution to these challenges, offering innovative tools for forecasting and managing technical risks. By utilizing machine learning algorithms, data analytics, and sophisticated modeling techniques, AI can analyze vast quantities of data, identify patterns, and predict potential issues with greater accuracy and speed than traditional methods. AI is now being applied in a wide range of industries, including finance, manufacturing, energy, healthcare, and cybersecurity, where its ability to process real-time data and learn from past events enables organizations to take proactive measures against potential risks.

This paper examines the growing role of AI in technical risk management, highlighting its key contributions and benefits. It explores how AI-driven systems can enhance predictive maintenance, improve decision-making processes, and reduce operational costs. Additionally, the paper addresses the challenges associated with AI implementation, such as data quality, algorithmic biases, and the need for integration with existing risk management frameworks. Through this analysis, the paper aims to demonstrate the transformative impact of AI on risk management practices and its potential to revolutionize how organizations approach technical risk forecasting and mitigation.

Recent research on business continuity and risk assessment highlights the potential of new technologies, particularly artificial intelligence (AI), to improve the effectiveness of risk management. Although some studies have explored AI's role in risk assessment, more research is needed to understand how specific AI technologies can significantly enhance risk prediction for business continuity. While many studies underscore AI's potential, there has been limited in-depth analysis of the various AI techniques and tools most beneficial in different corporate contexts. For instance, machine learning algorithms, natural language processing (NLP), data analytics, and predictive maintenance systems are some of the technologies categorized under AI. However, the relative effectiveness of these tools in addressing different types of risks and ensuring business continuity has not been thoroughly examined. Additionally, while the benefits of AI in risk assessment are becoming more recognized, there is still a lack of empirical evidence quantifying improvements in accuracy, efficiency, and overall business continuity due to AI adoption. Organizations need concrete data to inform their investments in AI-driven risk management solutions.

Organizations are increasingly focused on identifying, assessing, and mitigating risks that threaten their continuity. Jackson et al. (2023) argue that AI has become a transformative tool for addressing these challenges. AI capabilities, such as machine learning, NLP, data analytics, and predictive maintenance, play a critical role in improving risk prediction for business continuity. Each of these AI technologies offers unique advantages in enhancing preparedness and resilience. According to Brintrup et al. (2023) and Raza (2023), AI-driven predictive maintenance is particularly effective at ensuring operational continuity. By analyzing sensor data and equipment performance, AI can predict when machinery or infrastructure is likely to fail, enabling preventive action to minimize unplanned downtime—a key aspect of business continuity, especially in industrial and critical infrastructure sectors.

II. Methods

AI has the capability to process vast amounts of data at remarkable speeds, uncovering patterns and insights that would be difficult for humans to detect. This technology is being applied to transform business forecasting by integrating advanced AI techniques with traditional financial practices, resulting in higher levels of accuracy and efficiency.

Historically, forecasting, budgeting, and variance analysis have relied on manual processes and historical data. However, with the increasing complexity and volatility of markets, there is a growing demand for more agile, data-driven approaches. AI leverages sophisticated algorithms and machine learning to process information from diverse sources, identifying hidden patterns and providing predictions that surpass human abilities.

Traditional financial forecasting methods, such as time series analysis, involve tracking data points at regular intervals and often use techniques like moving averages or exponential smoothing to filter out noise and reveal trends. AI enhances these methods by using deep learning and neural networks, which can detect more intricate patterns in the data. This leads to more accurate predictions of market behavior, revenue, profit margins, and other financial metrics. Additionally, AI continually refines its models, adjusting its calculations in real-time to improve forecast precision.

These tools are becoming easier for all parts of the business to deploy; now finance has the ability to see further into the future by joining with these efforts in partnership with the business and within the office of the CFO. Here are some brief examples:

Demand Forecasting:

- E-commerce Business: An e-commerce giant heavily relies on AI for demand forecasting. Their sophisticated AI models analyze historical sales data, customer behavior, seasonality and external factors to predict future demand accurately. This allows them to optimize inventory levels, minimize stockouts and reduce excess inventory costs, resulting in improved customer satisfaction and operational efficiency.
- Healthcare: Hospitals and healthcare providers use AI to predict patient admission rates and optimize resource allocation. AI models can help hospitals adjust staffing levels, manage bed availability, etc., by considering factors like historical patient data, seasonality and disease outbreaks.
- Content Strategy: Streaming companies are utilizing AI algorithms to forecast viewer preferences and predict the success of potential content offerings. They gain insights by analyzing viewer behavior, including viewers watching habits, search history and ratings. Companies can tailor their content creation and acquisition strategies. This data-driven approach has contributed to the reputation for producing highly engaging and successful original shows and movies.

Supply Chain: Retail Inventory Management: Retail chains leverage AI to optimize inventory levels across their stores. It analyzes sales data, foot traffic, and external factors like weather. AI systems can also provide recommendations on replenishment quantities and timing. This minimizes overstocking and understocking issues that lead to improved profitability and customer satisfaction.

Operations: Energy Consumption Prediction: Utility companies employ AI to forecast energy consumption patterns. By considering historical usage, weather forecasts and economic indicators, AI models can predict peak demand periods and engage users to optimize their energy consumption. This helps prevent power shortages during high-demand periods and enhances overall grid stability.

These real-world examples underscore the transformative impact of AI-driven approaches in financial processes. By leveraging AI's analytical capability, businesses gain a competitive edge by making data-informed decisions and staying ahead of market dynamics. However, it's important to note that while AI offers tremendous potential, its success depends on high-quality data, robust model training and ongoing validation to ensure accurate and reliable results.

III. Results

AI-driven financial analysis offers significant potential for improving decision-making, but it also faces several challenges and limitations, as you’ve outlined. Here’s a closer look at each:

1. Data Quality and Quantity:

- Challenges: Financial analysis depends heavily on accurate, comprehensive data. Poor data quality (incomplete, outdated, or erroneous data) can lead to incorrect predictions and analyses. Additionally, many businesses may not have access to the vast amount of historical data required to train AI models effectively.

- Mitigation: Businesses need robust data governance frameworks to ensure data integrity, and techniques like data augmentation can help alleviate some issues with limited datasets.

2. Model Overfitting:

- Challenges: Overfitting occurs when a model learns the noise and specific patterns in training data, resulting in poor performance on new, unseen data. In financial analysis, market anomalies and time-specific events can cause a model to overfit if not properly controlled.

- Mitigation: Regularization techniques, cross-validation, and robust testing on diverse datasets can help minimize overfitting, ensuring models are better suited for generalization across different market conditions.

3. Volatility and Uncertainty:

- Challenges: Financial markets are volatile and prone to unpredictable events like black swan events, market crashes, or geopolitical upheavals. AI models, trained on historical data, often struggle to predict such sudden, extreme events due to their reliance on past patterns.

- Mitigation: Combining AI models with scenario analysis, stress testing, and human oversight can improve preparedness for unexpected market shifts. AI models can also be complemented with alternative data sources, such as real-time news sentiment analysis, to capture emerging risks.

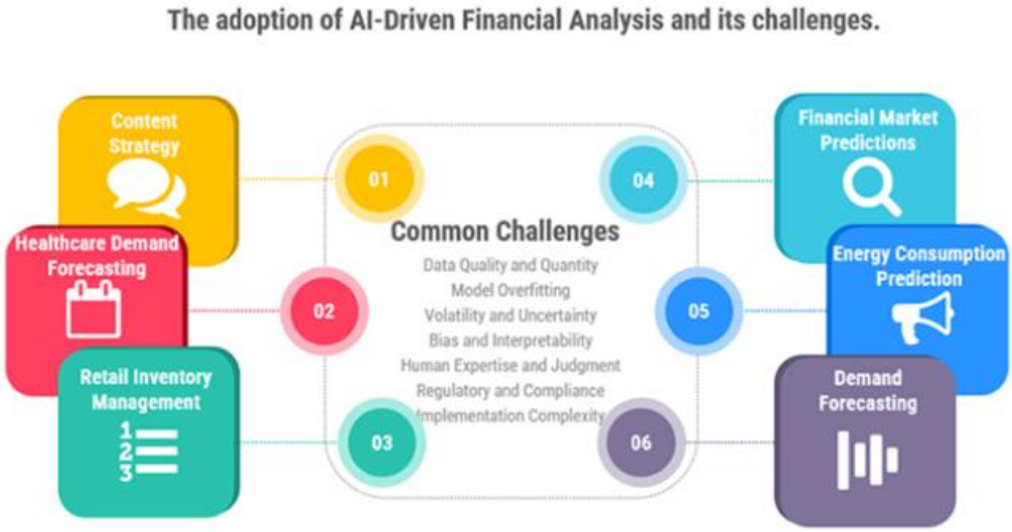

Figure 1: *AI-driven approaches in financial processes*

4. Bias and Interpretability:

- Challenges: AI models can inherit biases from the historical data they're trained on, potentially reinforcing existing disparities in predictions. Furthermore, many complex AI models (like deep learning) act as "black boxes," making it difficult to understand or explain the reasoning behind their decisions, which can hinder trust and regulatory compliance.

- Mitigation: Explainable AI (XAI) techniques are being developed to make models more transparent. Auditing AI predictions for biases and implementing fairness checks can help ensure the model's outputs are reliable and compliant with ethical standards.

5. Human Expertise and Judgment:

- Challenges: Despite AI's computational power, human expertise is still required to interpret nuanced situations and make strategic decisions. AI may struggle to handle highly context-dependent decisions where qualitative factors or unique market insights are involved.

- Mitigation: AI should be seen as a decision-support tool, augmenting human judgment rather than replacing it. Human oversight and collaboration between domain experts and data scientists are crucial for making well-rounded decisions.

6. Regulatory and Compliance Challenges:

- Challenges: Financial institutions must adhere to strict regulations, which can change frequently. AI models must be agile enough to adapt to new regulations while ensuring compliance. Failure to do so can lead to legal and reputational risks.

- Mitigation: A regulatory-aware AI framework can be developed to track and incorporate changes in regulations. Additionally, strong collaboration with legal teams and the integration of compliance checks into the AI model development lifecycle are essential.

7. Cost and Implementation Complexity:

- Challenges: Developing and maintaining AI models in financial analysis is resource-intensive, requiring substantial investments in infrastructure, skilled personnel, and ongoing updates. Smaller businesses may find these costs prohibitive.

- Mitigation: Cloud-based AI services and off-the-shelf AI tools can lower the barrier to entry. Additionally, firms can focus on modular implementations, starting small and expanding their AI capabilities as their resources allow.

These challenges reflect the complexity of integrating AI into financial analysis but also highlight areas where careful planning, regulation, and human involvement can enhance its effectiveness.

IV. Discussion

While AI offers tremendous potential in financial analysis, it's essential to approach its implementation with a clear understanding of its limitations and potential risks. The above real-world examples underscore the transformative impact of AI-driven approaches in financial processes, and addressing the mentioned challenges requires rigorous data preprocessing, model validation, ongoing monitoring and expert human oversight in each area of operations.

It is interesting to refer to Gartner 2023 - Hype Cycle for Artificial Intelligence, which shows the high adoption of AI innovations and techniques and how they are going towards the peak of inflated expectations. We may be at "peak AI" hype now and we may see headlines receding. Don't be fooled; this market is already taking off and people are hard at work finding ways to infuse AI into all parts of industry and our lives. Our role today is to acknowledge AI's potential, work to overcome challenges, and create an AI-driven culture with a holistic adoption into day-to-day finance operations.

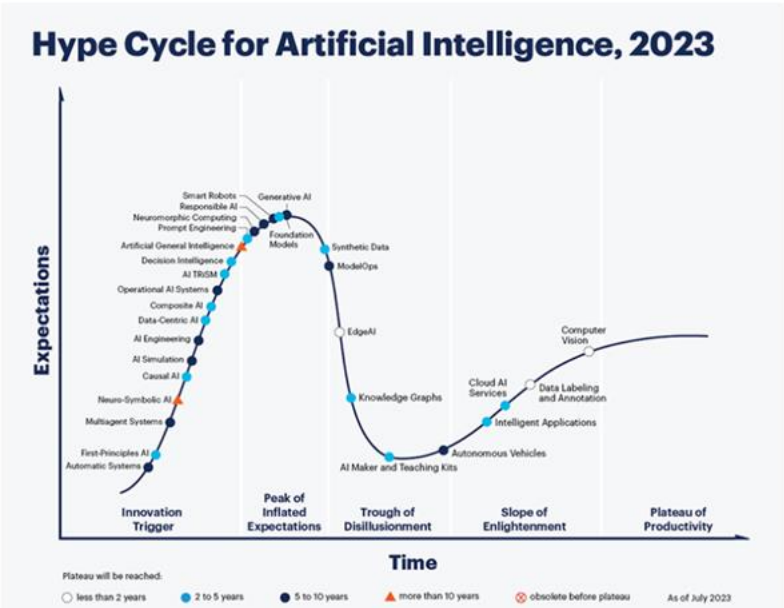

Figure 2: *Hype Cycle for Artificial Intelligence*

Based on the results of this study, several practical recommendations can be made for the financial industry to implement and use artificial intelligence (AI) to improve financial forecasting and reduce risks in the context of a global crisis.

First, financial institutions need to significantly invest in the technological infrastructure to support the implementation of AI. This includes purchasing the necessary hardware and software, as well as increasing the volume of data storage and processing power. A reliable infrastructure will ensure the optimal operation of AI-based forecasting systems and will allow for the efficient processing of large volumes of data for real-time analysis.

Second, it is important for financial institutions to train staff in the skills of working with AI and interpreting its results. The training should cover an understanding of AI algorithms, data analysis and forecasting methods. With sufficient skills, employees will be able to make better and faster decisions using AI technologies.

Third, financial institutions should develop adaptive and flexible AI models that can quickly respond to changing market conditions. Models that can adapt to changing data and the market environment will be more effective in forecasting accuracy during times of crisis. It is important to implement machine learning techniques that automatically update models based on new data.

Fourth, the integration of AI technologies with existing risk management systems must be done carefully to ensure that both systems function smoothly. Financial institutions need to develop processes that ensure that the results of AI models are effectively integrated into risk management strategies and applied in practice.

Fifth, a key factor in the success of AI models is good data governance. Financial institutions need to implement best practices for collecting, storing, and processing data to ensure its quality and integrity. This includes ensuring that the data is clean, relevant, and free from bias that could affect the accuracy of forecasts.

Sixth, financial institutions need to consider applicable ethical standards and legal requirements when implementing AI. Transparency of AI algorithms and the decisions made based on them, as well as data protection, should be a priority to prevent ethical and legal violations. It is important that the use of AI is compliant with all applicable regulations and that all decisions based on AI results are justified.

Finally, financial institutions should regularly evaluate the performance of AI models and make adjustments as necessary to improve their accuracy and effectiveness. Regularly evaluating and updating models ensures that AI technologies remain relevant and effective in addressing new challenges that arise during a crisis.

By following these recommendations, financial institutions will be able to effectively use AI to improve forecasting and risk management, allowing them to better manage uncertainty and increase the resilience of financial systems to unexpected risks.

METHODOLOGY OF ASSESSING TERRITORIAL RISKS OF THE ARCTIC ZONE OF KRASNOYARSK REGION IN THE IMPLEMENTATION OF INVESTMENT PROJECTS

Ulyana Postnikova

•

Mechanical Engineering Research Institute of the RAS, RUSSIA
ulyana-ivanova@inbox.ru

Abstract

The work is aimed at developing effective methods and models for solving problems in the field of analyzing the safety and security of Northern and Arctic territories in the context of multifactorial impacts (intensified development, implementation of investment projects, climate change), including identification of hazard factors, assessment of current and future man-made risks and security. To establish cause-and-effect relationships of the hazard factor's impact on the safety and sustainability of territories, it is proposed to use probabilistic graphical models based on Bayesian networks. The work was tested using the example of the Arctic territories of the Krasnoyarsk Region.

Keywords: climate change, technogenic hazards, territorial risks, safety

I. Introduction

One of the key problems of our time is adaptation to climate change. The international community is making attempts to solve this problem at the global level (Kyoto Protocol, Paris Agreement on Climate), but no significant results have been achieved. The problem is especially acute in the Arctic Zone (AZ), which is the most vulnerable territory to climate change.

According to the forecasts of the Intergovernmental Panel on Climate Change (IPCC), in the foreseeable future the Arctic territories may face the following problems [1-3]:

– - reduction in the extent of sea ice in the Arctic Ocean;
– - degradation of permafrost;
– - melting of the Greenland ice shield;
– - northward shift of the boundaries of natural zones and habitats of biological species.

One of the key problems of socio-economic development of the Arctic territories is associated with the melting of permafrost [3]. In the Strategies for the Development of the Arctic Zone and the Siberian Federal District of the Russian Federation for the Period up to 2035 [4, 5], from the standpoint of ensuring national security, one of the key factors influencing socio-economic development is changing climatic conditions, which contribute to the emergence of both new economic opportunities and risks for economic activity and the environment. Climate change leads to a decrease in the load-bearing capacity of buildings and structures, the integrity of industrial facilities and critical infrastructure is disrupted, which leads to the emergence of additional natural and man-made hazards, as well as significant economic losses associated with a reduction in service life, costs for maintenance, repair and reconstruction, and replacement of equipment earlier than planned. Accidents that occur in the networks of telephone, water or electricity supply can lead to serious consequences, up to and including the decision to evacuate the population [6, 7]. In these conditions, issues of technogenic safety acquire primary importance, since they determine the prospects for the development of territories, which makes research absolutely relevant.

The purpose of this work is to analyze technogenic safety in the implementation of investment projects taking into account natural and climatic factors based on a risk-oriented approach with subsequent testing on the example of the Arctic territories of the Krasnoyarsk Region.

The Arctic zone of Krasnoyarsk Region has a number of features:

- the climate of the territory belongs to the absolutely uncomfortable zone (the average annual temperature in January is -50°C);
- the landscape of the territory is represented by the Arctic desert, tundra and forest-tundra;
- a significant part of the territory is glaciers and permafrost (up to 46.2% of the total area of the Krasnoyarsk Region);
- active industrial development: mining, fuel (oil and gas), metallurgy, food industries, production and distribution of electricity, gas and water.
- high frequency of dangerous natural phenomena (storms, hurricanes, squalls, snowfalls, heavy ice, frost, blizzards, fog, frost, avalanches, heavy waves, coastal ice breakaway, floods, low water levels, early freeze-up, wildfires, etc.).
- high man-made load (occurrence of accidents in transport systems, industrial facilities, life support systems).

The Arctic zone of Krasnoyarsk Region includes 4 municipalities: Norilsk, Taimyrsky Dolgano-Nenetsky, Turukhansky and Evenkiysky districts. The total area of the AZ is 1854.5 thousand km^2, where more than 230 thousand people live.

Most of the Arctic territories are only subject to development, the main economic activity is concentrated in populated areas and along linear objects of transport infrastructure, thus climatic features and man-made load lead to destabilization of the natural system, to the emergence of environmental problems and a decrease in the quality of human life in extreme living conditions. In this situation, ensuring natural and man-made sustainability, increasing the security of the population and territories is possible only with an integrated approach to planning and managing development risks [8].

II. Methods

For sustainable development and functioning of territorial systems in conditions of multifactorial impact (intensified development, implementation of investment projects, climate change, etc.), it is necessary to analyze and assess both current risks and possible new threats.

Figure 1 shows a step-by-step scheme for analyzing the safety of a territory during the implementation of investment projects.

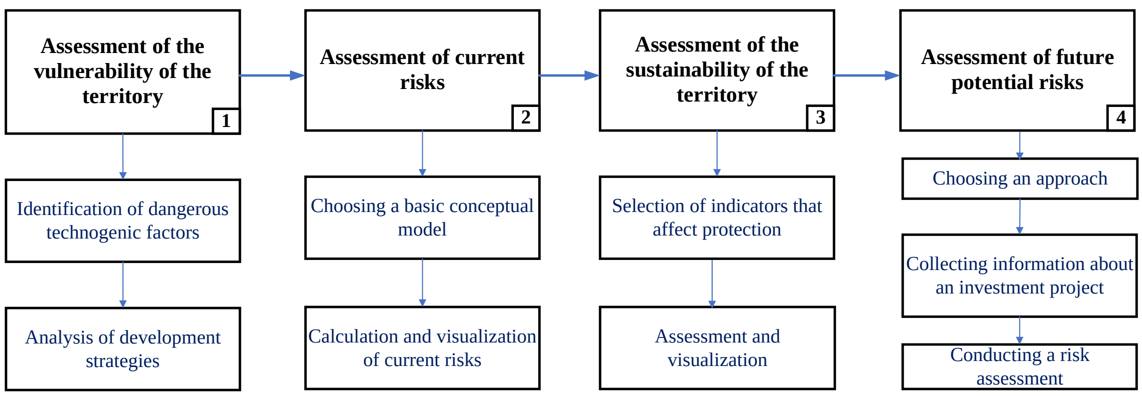

Figure 1: *Area Security Analysis Scheme*

At the first stage, when assessing the vulnerability of the territory, it is necessary to identify existing hazardous factors and analyze development strategies (activities) aimed at attracting new investors and stimulating industrial production.

At the second stage, when assessing current risks, it is necessary to select a mathematical model. In the work, to establish cause-and-effect relationships of the influence of hazard factors on the safety and sustainability of territories, it is proposed to use probabilistic-graphical models based on Bayesian networks. Bayesian networks combine the mathematical apparatus of probability theory and graph theory [9-11]. The basic idea of constructing a graphical model is related to the concept of modularity, i.e. decomposition of a complex system into simple elements. The probability of an event for each graph is determined by the formula for total probability. If event A can only occur when one of the events B_1, B_2… B_n, which form a complete group of incompatible events, is executed, then the probability of event A is calculated using formula (1):

$$P(A) = P(B_1) \cdot P(A \mid B_1) + P(B_2) \cdot P(A \mid B_2) + \cdots + P(B_n) \cdot P(A \mid B_n) \qquad (1)$$

To calculate the conditional probabilities of a given event, the Bayes formula (2) is introduced:

$$P(A \mid B_i) = \frac{P(B_i) \cdot P(A \mid B_i)}{P(B_1) \cdot P(A \mid B_1) + P(B_2) \cdot P(A \mid B_2) + \ldots P(B_n) \cdot P(A \mid B_n)} \qquad (2)$$

The assessment of the current risk for each hazardous factor is determined on the basis of the obtained values of probability and damage (3):

$$R_t = P_i \cdot U_i \qquad (3)$$

where P_i is the probability of occurrence of a certain risk factor; U_i is the damage from a certain risk factor, million rubles (data obtained from the official database of the Russian Emergencies Ministry).

At the third stage, we determined the sustainability (protection) of the territory. Technogenic protection of the territory is understood as a set of factors and measures that ensure the safety of the technosphere in the event of emergencies and disasters. Table 1 presents a list of indicators that affect the sustainability of the territory to occurrence of hazards.

Table 1: *Sustainability (protection) indicators*

List	Normative values	Normative documents
Fire departments	Estimated ratio of the dependence of the rescuers number on the population density	Organizational and methodological recommendations for determining the number of firefighting services of a constituent entity of the Russian Federation and its technical equipment
Emergency rescue teams	Calculated ratio of the dependence of the number of formations on the number of hazardous industrial facilities	Order of the Ministry of Health of the Russian Federation dated 27.02.2016 No. 132n "On the requirements for the placement of medical organizations of the state healthcare system and the municipal healthcare system based on the needs of the population"
Medical organizations	Depending on the population size	Orders and Decisions of the subjects of the Siberian Federal District "On approval of the list of potentially dangerous objects".

Quantitative values of protection are determined on the basis of the proposed formula (4):

$$Z_{(\tau)} = \frac{1}{3}\left(\frac{N^{A}_{\text{FD}}}{N^{S}_{\text{FD}}} + \frac{N^{A}_{MO}}{N^{S}_{MO}} + \frac{N^{A}_{ER}}{N^{A}_{HIF}}\right) \cdot 100 \geq 100\% \quad (4)$$

где N^{A}_{FD}/ N^{S}_{FD} – actual/standard number of fire stations in the territory under consideration; N^{A}_{MO}/ N^{S}_{MO} – actual/standard number of medical institutions in the territory under consideration; $N^{\Phi}_{\text{АСФ}}$ - the actual number of emergency rescue teams in the territory under consideration; N^{A}_{HIF} - the actual number of hazardous industrial facilities in the territory under consideration..

At the fourth stage, it is necessary to assess the possible risks from the implementation of investment projects in the territory under consideration. It is recommended to analyze possible hazardous events using probabilistic-graphical models, which allows assessing the combined impact of current and future risks.

III. Results

For the Arctic zone of Krasnoyarsk Region, the main dangerous man-made factors were identified, presented in Figure 2. Based on this graphical model, the probabilities of occurrence of events and risk values for each factor are determined. According to the proposed algorithm, state programs and plans for the development of the Arctic zone of Krasnoyarsk Region were further analyzed, which are aimed at creating a regional transport and energy infrastructure, and forming high-tech and competitive territorial clusters.

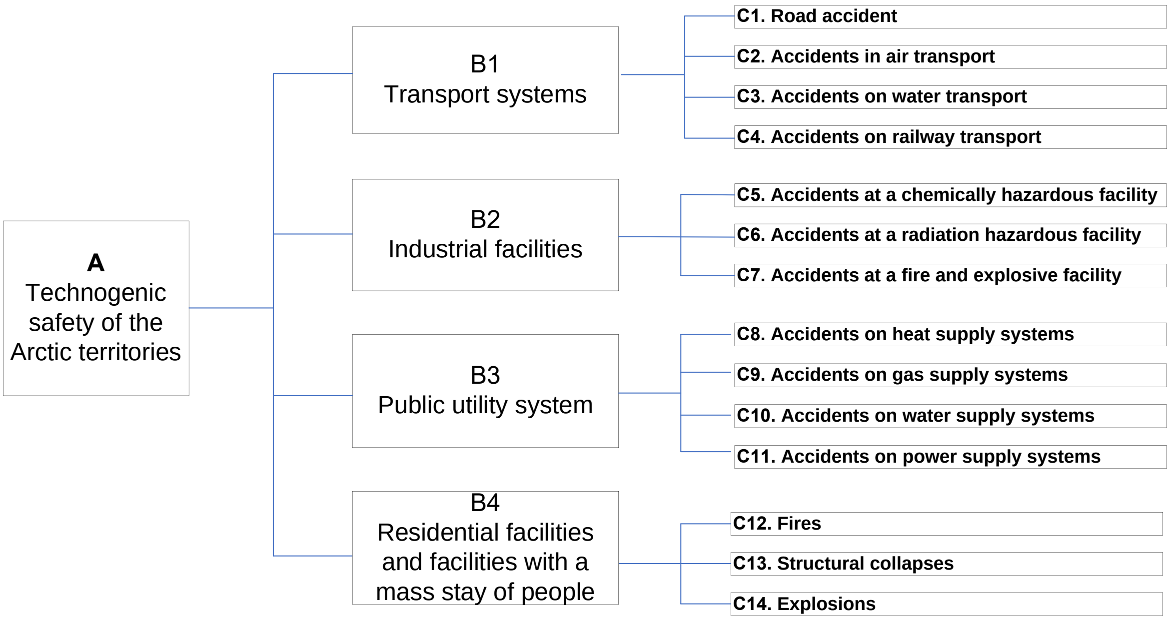

Figure 2: *List of man-made hazards*

Key investment projects for the development of the Arctic zone of Krasnoyarsk Region include [4]:

- creation of a network of latitudinal and meridional railways;
- development of the infrastructure of the Northern Sea Route;
- creation of a new large mining and metallurgical complex in the Norilsk industrial region - the "Southern Cluster" Project;
- development of oil and gas fields;
- gasification of the Krasnoyarsk agglomeration based on the associated gas resources of Evenkiysky district;

- renovation of the housing and communal services of the Norilsk agglomeration;
- development of Arctic and northern tourism.

To assess the current territorial man-made risk, it is necessary to determine the probability of a hazardous event. Figure 3 shows probability distribution diagrams for event groups.

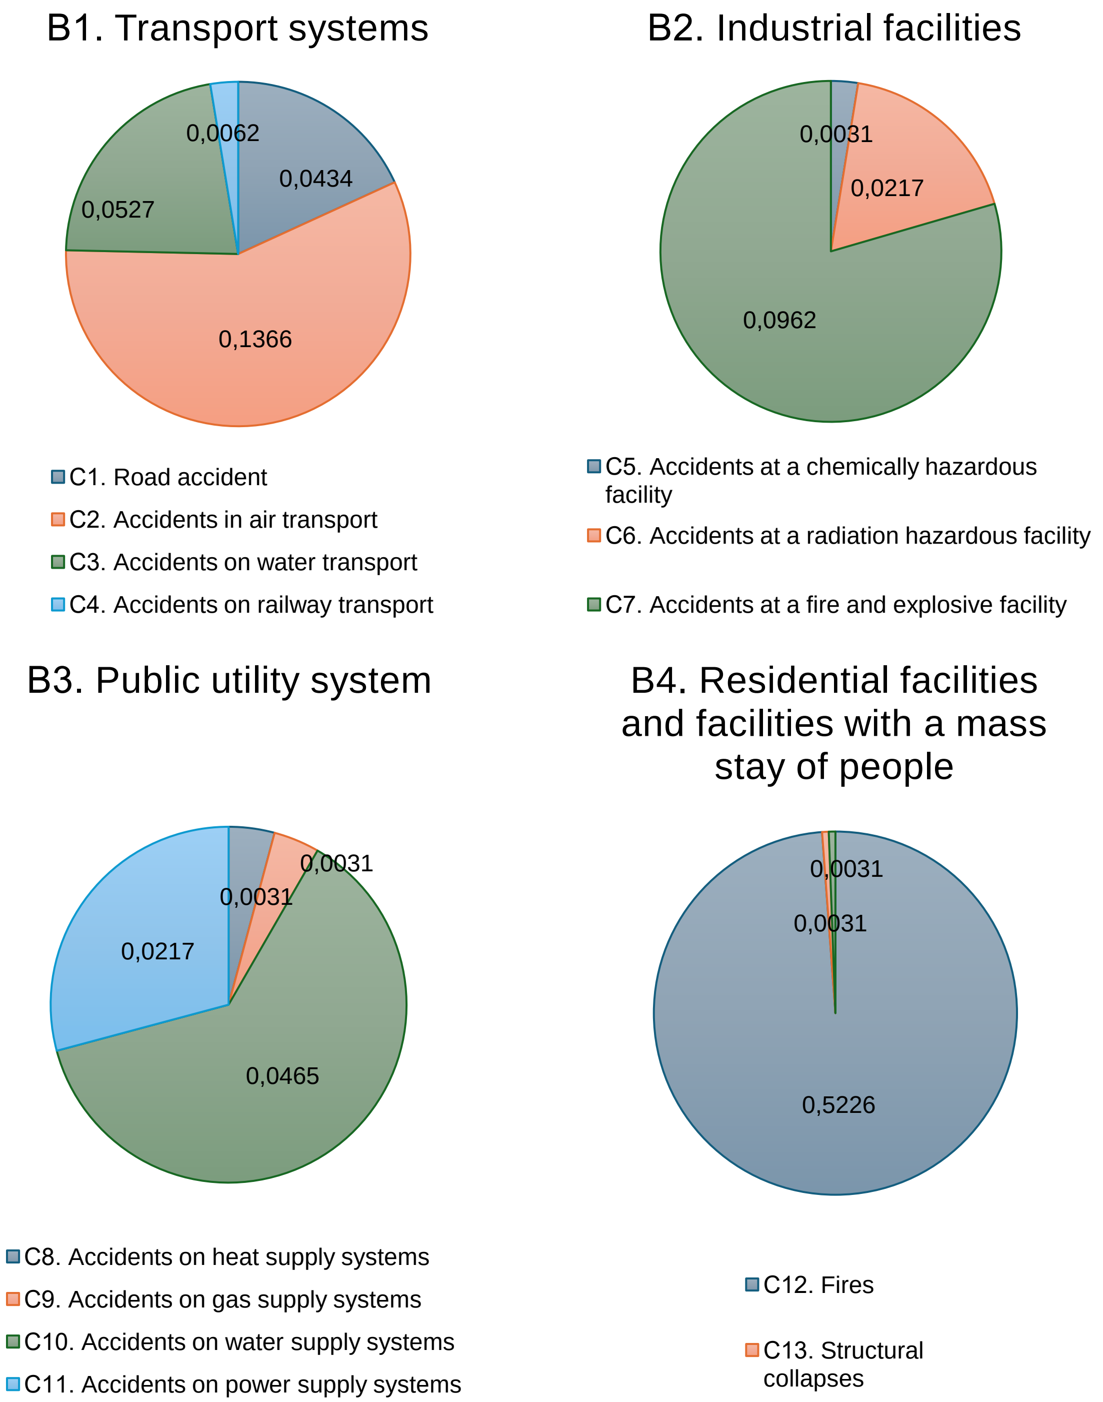

Figure 3: *Probability distribution across event groups*

Based on the obtained results of probability calculation, it can be concluded that the most frequent occurrences are fires, accidents on air transport, at fire-explosion hazardous facilities and on power grids.

Table 2 presents the results of the assessment of territorial man-made risks for each municipality of the Arctic zone and the level of protection.

Table 2: *Territorial man-made risk of the Arctic zone of Krasnoyarsk Region*

The name of the main factors	**The risk of a dangerous factor**			
	Taimyrsky Dolgano-Nenetsky district	Evenkiysky district	Turukhansky district	Norilsk city
Transport systems	$4{,}8 \cdot 10^{-2}$	$5{,}2 \cdot 10^{-2}$	$3{,}6 \cdot 10^{-2}$	$8{,}1 \cdot 10^{-2}$
Industrial facilities	$6{,}1 \cdot 10^{-3}$	$3{,}7 \cdot 10^{-2}$	$1{,}2 \cdot 10^{-2}$	$6{,}4 \cdot 10^{-2}$
Public utility system	$1{,}2 \cdot 10^{-2}$	$1{,}5 \cdot 10^{-2}$	-	$4{,}3 \cdot 10^{-2}$
Residential facilities and facilities with a mass stay of people	$3{,}9 \cdot 10^{-2}$	$1{,}4 \cdot 10^{-1}$	$6{,}5 \cdot 10^{-2}$	$3{,}03 \cdot 10^{-1}$
	The level of protection of territories			
	17%	37%	34%	39%

The Taimyr Dolgano-Nenets and Turukhansky districts are at risk of air transport accidents. The Evenki district has the highest risk of household fires. The greatest man-made hazard is concentrated in Norilsk, which is due to the high population (in comparison with municipal districts), the number of potentially dangerous objects and the intensive traffic of the Norilsk airport. Having identified the dangers arising in the territory, it is necessary to analyze its ability to withstand threats. Municipalities of the Arctic zone have a low level of protection. For the city of Norilsk, Taimyrsky Dolgano-Nenets and Turukhansky districts there are not enough emergency rescue teams, fire departments and medical institutions. For the Evenki district there are not enough fire departments and emergency rescue teams.

When assessing possible future man-made risks, we will consider the emergence of additional threats associated with the creation of a large mining and metallurgical complex in the Norilsk industrial region. We will consider a common scenario of a fire and explosion associated with blasting operations. Fig. 4 shows a probabilistic graphical model for analyzing this scenario.

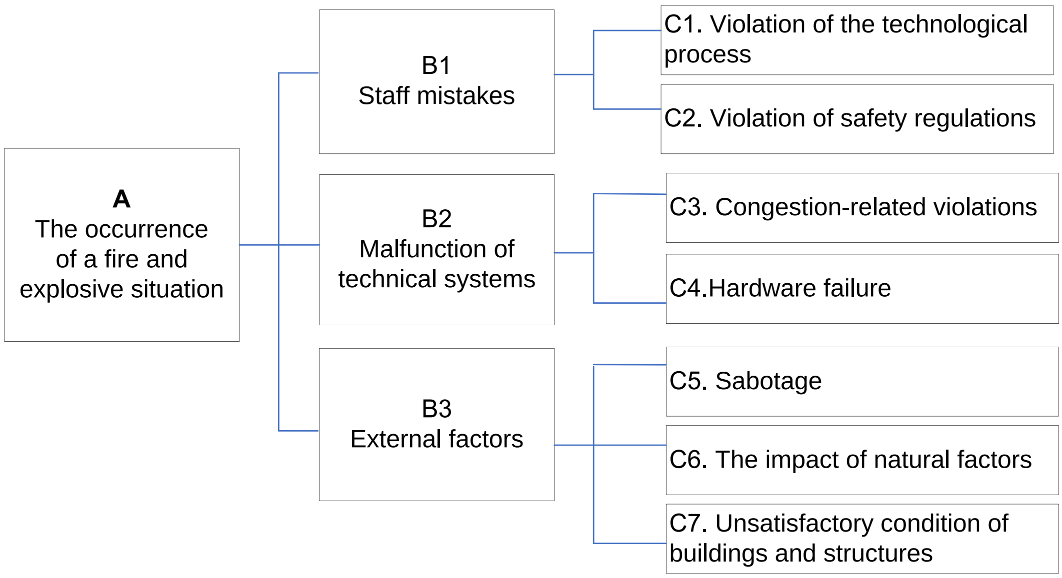

Figure 4: *Cause-and-effect patterns of occurrence of a fire-explosion hazardous situation*

The probability of occurrence of a fire and explosion hazardous situation is 5.6·10-6, the damage from the implementation of this scenario is about 200 million rubles. Thus, the territorial man-made risk from the occurrence of industrial accidents for the city of Norilsk increases from 6.4·10-2 to 6.51·10-2 and this is taking into account one possible accident scenario. Thus, with an insufficient level of protection, high current man-made territorial risks, the implementation of investment projects should be carried out with increased control by the state. Development and exploration of territories should be without damage to future generations.

IV. Discussion

Active industrial development of northern and arctic territories, the development of infrastructure projects and clusters, taking into account special natural and climatic conditions leads to a dilemma between economic growth and an increase in the number of potential dangers associated with the growth in the number of industrial facilities.

Thus, the management of territorial entities should be based on the methodology of risk and security assessment within the framework of the concept of sustainable development and the leading priority of the socio-economic and scientific-technical development of Russia - the security of society and the state. Prevention of hazards can be effective only with the development of a methodological complex of territorial analysis based on a risk-oriented approach.

Man-made systems, natural processes, and territorial formations are subject to the impact of characteristic types of risk that must be specifically identified and necessary measures taken to protect and mitigate the consequences in the event of a hazard, which is especially important for Arctic territories with unique natural complexes, the impact on which can lead to catastrophic consequences.

Abstract

The following paper looks into the development of a comprehensive toolkit for analyzing entrepreneurial ecosystems. The work is examines in the context of the modern digital economy, based on a theoretical and methodological approach.
The dynamic conditions of digital transformation, against the backdrop of global economic instability, have sparked both scientific and practical interest in studying entrepreneurial ecosystems (EEs).
The authors critically examine approaches to defining the essence of entrepreneurial ecosystems, as well as the directions of applied and fundamental research that shape the core areas of related scientific interests. Systematizing the spheres of academic focus within the context of EE research, the authors conclude that, in Russia, particular attention is paid to regional entrepreneurial system development, sustainable development principles, and the assessment of the impact of the digital environment.
The following work studies key ideas underlying ecosystem concepts such as evolutionary theory, organizational ecology, neo-institutional theory, dynamic capabilities theory, and as well as the modular structure. The authors of this paper conclude that an entrepreneurial ecosystem is a complex interaction system, carried out through the creation of network effects and a special connection between cooperation, competition, innovation etc.
It is also essential to mention that by examining the key components of EEs and the fundamental principles of their functioning, the authors of the work outlined major research tracks related to core aspects of entrepreneurship ecosystems:
Access to resources and startup support,
The role of government influence on EE development,
Innovation issues and the commercialization potential of innovative products.
The authors were able to develop a theoretical and methodological approach to studying entrepreneurial ecosystems and classify EEs based on key characteristics.

Keywords: entrepreneurial ecosystems, theoretical and methodological approach, ecosystem actors, classification features of PES, ecosystem concepts

I. Introduction

The current conditions of digital transformation and global economic instability have fueled interest in studying the concept of entrepreneurial ecosystems as one of the mechanisms for business and innovation development. Modern research on entrepreneurial ecosystems progresses in various directions, reflecting a wide spectrum of scientific interests. The main areas can be grouped by themes, as presented in Fig. 1.

1. General Concept of Entrepreneurial Ecosystems

- Application of ecosystem concepts in economic and management research (Ramenskaya L.A.): This work offers theoretical foundations and methodological approaches for analyzing ecosystems in management, including the role of interactions between participants.
- Meaningful analysis of innovation, business, and entrepreneurial ecosystem concepts (Burda Ye.D. et al.): This study covers a conceptual analysis of innovation and entrepreneurial ecosystems, emphasizing innovation and entrepreneurship within ecosystems

2. Entrepreneurial Ecosystems in the Post-Crisis Economy

- A New Entrepreneurial Policy for Russia After the 2020 Crisis (Zemtsov S.P. et al.): The authors examine the opportunities and challenges for the development of entrepreneurial ecosystems in Russia following the COVID-19 pandemic.
- The Role of Entrepreneurship in the Sustainable Development of Rural Areas in Russia (Polbitsyn S.N.): This study focuses on the development of rural areas through entrepreneurship, emphasizing the importance of ecosystems in ensuring sustainable growth.

3. Regional Features and Ecosystem Development in Russia

- Rural Entrepreneurial Ecosystems of Russia (Polbitsyn S.N.): The paper analyzes regional aspects of ecosystem development in rural areas.
- Assessing the Links Between Entrepreneurial Ecosystems and Economic Development Levels in Russian Regions (Ovchinnikova A.V., Zimin S.D.): This study focuses on analyzing the relationship between entrepreneurial ecosystems and the economic development of regions.

4. Technological Entrepreneurship

- Technological Entrepreneurship as a Factor in Russia's Development (Zemtsov S.P.): The research highlights the importance of technological entrepreneurship for long-term economic growth and innovation in Russia.

5. Post-Socialist Economies

- *Entrepreneurial Ecosystems in Post-Socialist Economies* (Chepurenko A.): This work focuses on the specifics of ecosystem development in post-socialist countries, where the institutional environment differs from Western models.

6. Digital Environment Factors

- *The Influence of Digital Environment Factors on the Development of Entrepreneurial Ecosystems in Russia's Regions* (Yakimova V.A., Pankova S.V.): This study addresses the impact of digitalization on the development of entrepreneurial ecosystems, with a focus on regional characteristics

7. International Cooperation and Investments

- *Stimulating Local Entrepreneurship Through Foreign Investments* (Machtama A., Sauka A.): This research analyzes the role of foreign investments in developing entrepreneurial ecosystems in various countries.

8. Innovation and Business Incubators

- *Business Incubators in Russia: A 2020 Survey in International Comparative Perspective* (Slesarev M.A.): This study examines the role of business incubators in Russia and their effectiveness in an international context.

Figure 1: *Systematization of scientific interests in the context of EE research*

Scholarly consensus on the essence of entrepreneurial ecosystems reveals that they are complex systems of interaction between various actors: entrepreneurs, government institutions, investors, and even educational institutions. Together, these entities create the conditions for the emergence and sustainable development of new business structures. The systemic approach applied to studying EEs allows for the identification of key factors influencing the dynamics and stability of such business structures and defines the roles of various participants in creating a favorable environment for entrepreneurial activity.

The relevance of the study is driven by the need to develop a comprehensive toolkit for analyzing entrepreneurial ecosystems in the modern digital economy. Integrating various methodological approaches, including systems analysis, network methods, and institutional theory, offers a deeper understanding of the relationship between actors and the conditions of their interaction. This article proposes a theoretical and methodological framework for researching entrepreneurial ecosystems, with a focus on identifying key structural elements and factors contributing to the development of entrepreneurship.

Thus, research on entrepreneurial ecosystems covers a wide range of aspects, from theoretical and methodological foundations to practical cases of ecosystem development in regions and specific industries. In Russia, particular attention is given to regional development, sustainable entrepreneurship in rural areas, and the impact of the digital environment. Innovation and technological entrepreneurship play a crucial role, particularly in post-crisis economies and post-socialist markets.

II. Methods

Several key methods were applied in the study, including bibliographic analysis, network analysis, and case study methods. The bibliographic analysis allowed for identifying the main scientific discourses and approaches to studying entrepreneurial ecosystems, based on publications from the last two decades. Network analysis was used to map interactions between ecosystem participants, revealing central actors and determining the structure of connections. The case study method, based on the study of specific ecosystems, such as Silicon Valley and Russian technoparks, allowed for a deeper examination of their functioning and the identification of critical success factors.

III. Results

The concept of an entrepreneurial ecosystem involves the creation of a network of autonomous organizations that jointly create value through cooperation and some degree of interdependence. Ecosystems can include various types of participants (commercial organizations, government agencies, NGOs, startups, and other entities) united by the idea that they interact for mutual benefit. However, competition remains, though it is governed by cooperative principles.

Let us examine the key ideas underlying the ecosystem concept:

1. Evolutionary theory and organizational ecology traditionally view ecosystems as biological analogs where participants compete and cooperate, adapting to changes. By applying concepts like "natural selection" and "ecological niches" to the life cycle of EEs, one can explain how these systems are created, survive, and evolve.

2. Neo-institutional theory distinguishes entrepreneurial ecosystems from other forms of systemic interaction, such as markets or entrepreneurial hierarchies. Applying this theory to EEs leads to an understanding of the role of institutions in coordinating system elements and reducing transaction costs through inter-institutional cooperation.

3. Dynamic capabilities theory emphasizes the ability of companies within ecosystems to adapt and transform their development strategies in response to ecosystem changes. This adaptability is key to achieving long-term competitiveness.

4. Modular structure suggests that while ecosystems consist of independent modules, they nonetheless exhibit a degree of interdependence a symbiosis that allows EE participants to create value together, even while maintaining their economic and legal autonomy. This trait is

particularly important for platform ecosystems, where large companies are embedded in a unique interaction architecture filled by its participants as individual modules.

Thus, an entrepreneurial ecosystem is a complex interaction system, where cooperation, competition, and innovation create network effects. The ecosystem enables the participating organizations (the system's modules) to jointly create products and services, discover new business models and solutions, reduce costs, and adapt their activities to external changes.

Let us consider and characterize the main components of the PES (Figure 2).

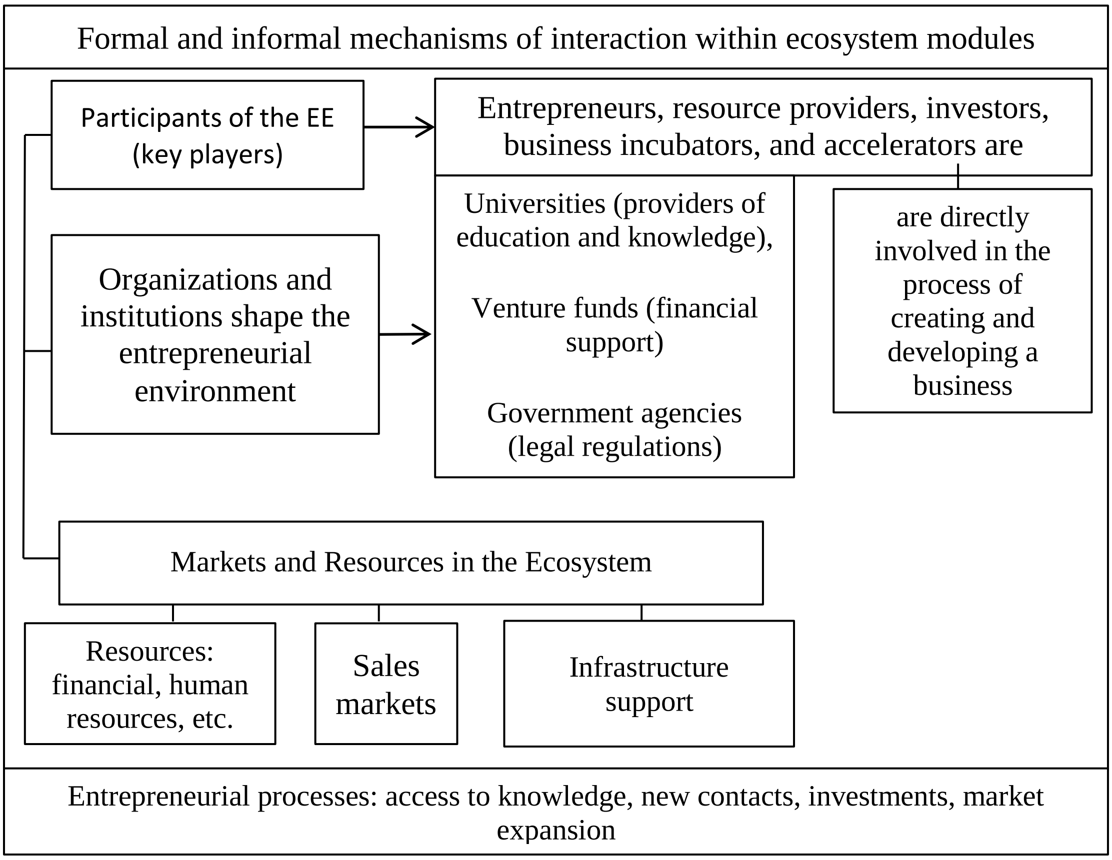

Figure 2: *Key Components of EEs*

The components of an EE, presented in Figure 2, interact based on several principles:

Interconnectedness and Interdependence;

Leadership;

Value Creation;

Flexibility and Adaptability

A classic example of an entrepreneurial ecosystem, which can serve as an academic model, is Silicon Valley. This ecosystem includes system modules such as entrepreneurs, investors, universities, technology companies, and startup creators. Through interaction, these components work together to create a favorable environment for innovation and technological entrepreneurship.

In Russia, analogous structures can be found in technoparks and innovation clusters, where the government provides funding through grants and other support programs.

IV. Discussion

Research into EEs develops along several lines, driven by regional context and the scientific interests of the authors. We have identified three main tracks, which systematize the body of research regarding the fundamental aspects of entrepreneurial ecosystems:

1. Research on access to resources and startup support as the main driver of innovation and project development. This track examines the availability of resources such as finances, knowledge, and connections.

2. Research on the role of government in the development of EEs and the possible or necessary degree of state control over EEs. In this context, the government is viewed as an actor that either facilitates or hinders the creation of conditions for the development of the ecosystem through a system of restrictions, regulations, and support.

3. Innovation and commercialization of innovative products: This track focuses on the innovative entrepreneurial activity of all ecosystem components. The reason for emphasizing this group of studies is that, through synergy, such structures create a collaborative effect that promotes the generation and implementation of new ideas, enhancing their chances of commercialization.

Based on the components of EEs and the principles by which these systems are created, operate, and evolve, as well as the basic research tracks, it is proposed that when creating a theoretical and methodological foundation for the study of these systems, the complex and multi-component nature of the ecosystem approach should be considered. This approach systematically links the connections between ecosystem participants, institutionalizing them and taking into account the processes the system undergoes throughout its lifecycle.

The proposed theoretical and methodological approach to EE research incorporates both theoretical and empirical methods, which will allow for the study of the dynamics, structure, and factors of successful ecosystem functioning.

1. Theoretical and Methodological Foundation of EE Research

1.1 Key Theories (Foundation of Research):

- Ecosystem Theory (Iansiti, Levien, 2004): This theory suggests that ecosystem participants are interdependent, develop together dynamically, and that their co-evolution contributes to value creation;
- Network Approach Theory (Granovetter, 1985): This theory emphasizes the importance of network connections between participants, forming channels for the exchange of resources, knowledge, and technologies;
- Innovation Systems Theory (Lundvall, 1992): This theory primarily considers innovation ecosystems as a key part of the entrepreneurial environment. It highlights the importance of creating such systems for startups and small companies, leveraging networks of partners and their resources to drive innovation;
- Institutional Theory (North, 1990): This theory underscores the role of institutional conditions (through the establishment and enforcement of legal, regulatory, cultural, and other norms) in entrepreneurial ecosystems. Established institutions support the entrepreneurial environment by providing access to resources and reducing transaction costs;

1.2 Research Principles:

- cystematicity: The ecosystem is viewed as a holistic system that includes interdependent elements (entrepreneurs, institutions, resources, infrastructure);
- multilevel Approach: This principle calls for conducting research on the ecosystem at different levels: micro (enterprises, entrepreneurs, startups), meso (local and regional systems), and macro (national ecosystem);
- interactivity: This principle is crucial due to the dynamic nature of EEs, which requires an analysis of the interactions between actors in the exchange of resources, knowledge, and support;
- adaptability: This principle reflects the constant variability of EEs, necessitating the application of flexible approaches to their study and management.

2. Research Methods and Tools

The research methods include both qualitative (descriptive) and quantitative methods.

2.1 Qualitative Methods may include:

- case Studies: The method of studying successful EE examples helps identify key success factors and lessons for other ecosystems;
- surveys of Key Actors: This allows for an understanding of their roles, motivations, and participation in the ecosystem, revealing the dynamics of interactions;
- content Analysis: The study of data presented in reports, results of strategy implementations by large companies and holdings, and evaluation of the effectiveness of government programs help determine key measures that support the development of EEs.

2.2 Quantitative Methods may include:

- social Network Analysis: This method allows for measuring and visualizing connections between various ecosystem participants. It helps identify key participants (leaders), those on the periphery, support modules, and other system elements. This analysis aids in assessing the density of connections, identifying cluster elements, and outlining the overall network architecture;
- statistical Analysis and Econometrics: Using regression models, this method evaluates the correlation between various factors (e.g., access to venture capital and startup success);
- benchmarking: Aimed at comparing different ecosystems, or one's case with a benchmark system, this helps identify factors that contribute to entrepreneurship growth and sustainability, as well as obstacles to it;
- entrepreneurial Ecosystem Development Indices: These indices allow for the evaluation of ecosystem development based on various criteria (access to financing, institutional support, level of innovation, etc.);

2.3 Data Collection Tools: In this case, traditional tools are used, such as secondary data analysis (official reports, statistics, analytical reviews, etc.) and surveys of entrepreneurs and representatives of key ecosystem actors.

3 Research Stages are shown in Figure 3

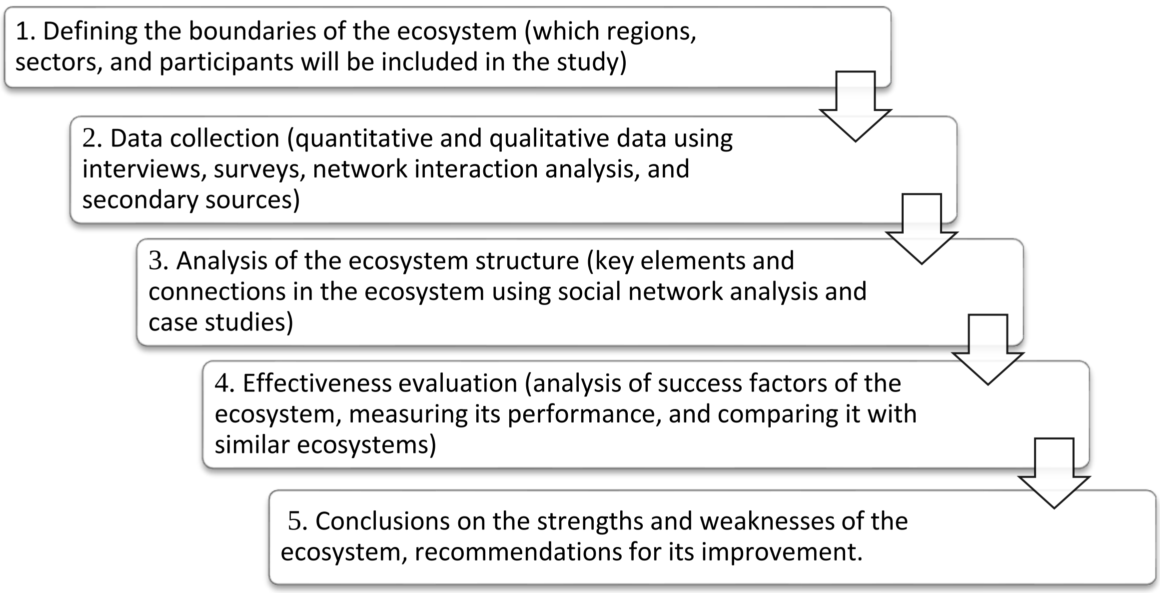

Figure 3: *Stages of Research on Entrepreneurial Ecosystems*

Thus, the proposed theoretical and methodological approach to the study of entrepreneurial ecosystems (EEs) meets the criteria of systematicity and multilevel analysis, combining theoretical and empirical methods for a joint analysis of the dynamics, structure, and factors that influence the functioning and development of ecosystems.

An essential condition for the scientific study of EEs is the systematization of characteristics that define their essence. The classification of EEs by their key features, as proposed by us, is presented in Table 1.

Table 1: *Classification of Entrepreneurial Ecosystems by Key Features*

Classification features	Subtypes	Description
1. Territorial Affiliation	Global Ecosystems:	Interactions and processes at the level of international business and global economies.
	National Ecosystems:	Characteristics of entrepreneurship within a single country.
	Regional Ecosystems:	Local business ecosystems in specific regions (cities, regions, rural areas).
2. Sectoral Focus	Technological Ecosystems:	Related to innovative and high-tech industries (IT, biotechnology, fintech, etc.).
	Agro-industrial Ecosystems:	Ecosystems in agriculture and agro-industry.
	Traditional Industries:	Include entrepreneurship in traditional economic sectors (trade, manufacturing, services).
3. Maturity Level	Nascent Ecosystems:	Ecosystems in the early stages, where infrastructure and connections between participants are still developing.
	Developing Ecosystems:	Ecosystems with basic infrastructure, actively growing through the adoption of technologies.
	Mature Ecosystems:	Stable ecosystems with well-established connections and a solid infrastructure.
4. Target Audience	Small and Medium-sized Enterprises (SMEs):	Ecosystems that support the development of small and medium-sized businesses.
	Large Companies:	Ecosystems interacting with large corporations and international players.
	Startups and Incubators:	Ecosystems aimed at supporting startups and business incubators.
5. Institutional Structure	University-based Ecosystems:	Include educational and research institutions as key elements.
	Corporate Ecosystems:	Ecosystems where large corporations play a leading role.
	Public-Private Partnerships:	Ecosystems developing with strong government support.
6. Technological Focus	Digital Ecosystems:	Structures based on digital technologies (blockchain, AI, Big Data, etc.).

	Analog Ecosystems:	Ecosystems with traditional business methods not related to digitalization.
7. Economic Model	Innovation-driven Ecosystems:	Focused on developing new products and services through innovation.
	Sustainability-oriented Ecosystems:	Include principles of ecological and sustainable growth.
	Investor-oriented Ecosystems:	Ecosystems focused on venture funding and investments.
8. Type of Interactions	Horizontal Ecosystems:	Interaction between participants of equal status.
	Vertical Ecosystems:	Interaction between participants at different levels, including startups and large companies.
9. Ecosystem Resources	Infrastructure-based Ecosystems:	Ecosystems where key roles are played by business incubators, coworking spaces, and technology parks.
	Financial Ecosystems:	Ecosystems focused on financial support (venture funds, grants, etc.).
	Cultural and Social Ecosystems:	Ecosystems that influence entrepreneurship through cultural and social factors.

In conclusion, the theoretical and methodological basis for the study of entrepreneurial ecosystems involves the integration of several theoretical approaches and the use of a wide range of methods and tools. To comprehensively study the ecosystem, a combination of qualitative and quantitative methods is necessary, such as social network analysis, case studies, interviews, and statistical analysis. This approach enables a deeper understanding of the structure and dynamics of the ecosystem and the development of measures to support and enhance it.

Acknowledgments.
The work was carried out within the framework of the state assignment of the Ministry of Science and Higher Education of the Russian Federation (topic No. 24-78-10011).

xedi1996@mail.ru
fidan.ismayilova.2014@mail.ru

Abstract

In this paper we analyzed the probabilities of accident development in case of liquefied hydrocarbon gas emission taking into account the logistic scheme of accident development. It was found that the probability of ignition of the release is determined by the probability of combustible substance coincidence with the ignition source. It should be borne in mind that the probability of ignition source manifestation depends on the area of the affected object (cloud of gas-air mixture or gas liquid).

Keywords: liquefied gas, risk, probability, accident, logistics scheme, spill combustion, gas-air mixture

I. Introduction

For risk analysis RD 03-48-01 [1] offers 6 methods of analysis. If the theory of risk corresponded to the probability theory, the best method of analysis would be quantitative analysis. Unfortunately, risk theory almost completely ignores the existing probability theory.

To demonstrate the dubiousness of the examination requirements, let us consider a method of analysis that uses an event tree logic diagram.

The logical scheme of the accident development associated with the release of combustible substances at an outdoor facility is presented in Fig. 1.

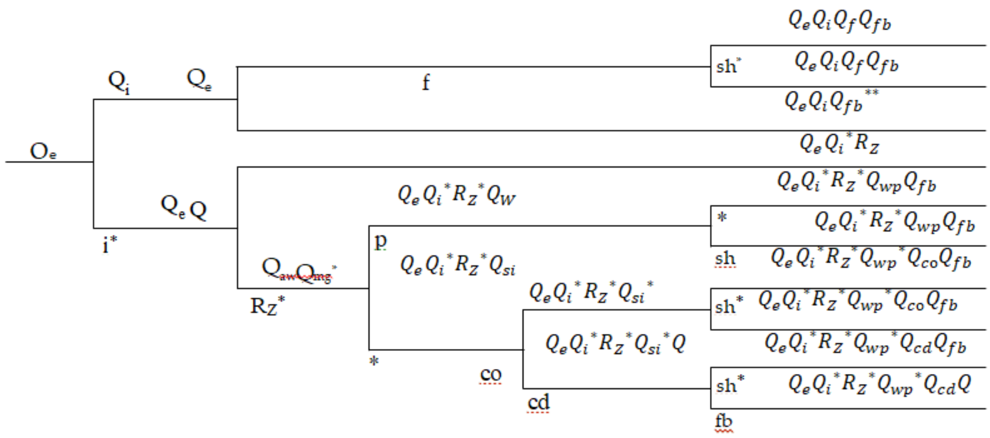

Figure 1: *Logic diagram of an accident involving the release of flammable substances at an outdoor facility*

Decoding of designations on the diagram:

A1 - instantaneous ignition of the flowing product followed by flaring combustion;

A2 - flare combustion, thermal effect of the flare leads to destruction of the nearby tank and formation of a fireball;

A3 - instantaneous release of product with formation of a fireball;

A4 - no instantaneous ignition, the accident is localized due to effective fire prevention measures or due to vapor cloud dissipation;

A5 - instantaneous flashover did not occur, fire prevention measures were not successful, spill ignition;

A6 - destruction of a nearby tank under the influence of excessive pressure or heat during burning of the spill or formation of a fireball;

A7 - combustion of a vapor-air mixture cloud;

A8 - destruction of a nearby tank under the influence of excessive pressure or heat during burning of a spill or formation of a fireball;

A9 - combustion of a cloud with development of overpressure in open space;

A10 - destruction of a nearby tank under the influence of excessive pressure or heat during burning of a spill or fireball formation;

Calculation of the probability Q(Ai) of each of the variants of realization of the logic circuit. For this purpose the following relations are used:

$$Q(Ai)= Q_e Q_i Q_f Q_{fb} Q_{fb}^{*}, \quad (1)$$

Qe - probability of emergency release of a combustible substance;

Qi - probability of instantaneous ignition of the flowing product;

Qf - probability of flare combustion of the jet of the expiring product;

Qfb - probability of destruction of a nearby tank under the influence of a fireball;

Qfb* - probability of preservation of the nearby tank under the influence of the fireball;

$$Q_{fb}^{*}= 1- Q_{fbh}. \quad (2)$$

$$Q(A2)= Q_e Q_i Q_f Q_{fb}, \quad (3)$$

$$Q(A3) = Q_e Q_i Q_{fb}^{**}, \quad (4)$$

Q_{fb}^{**} - is the probability of tank collapse with fireball formation.

$$Q(A4) = Q_e Q_i^{*} R_Z, \quad (5)$$

Qi is the probability that instantaneous ignition of the expiring product will not occur;

P3 - probability that the fire prevention means have fulfilled the task or there was a dispersion of the vapor-air mixture cloud.

$$Q(A5)= Q_e Q_i^{*} R_Z^{*} Q_{wp} Q_{fb}^{*}, \quad (6)$$

P3*=1-P3 probability of failure to fulfill the task by fire prevention means;

Qsi - probability of spill ignition;

$$Q(A6)= Qe\, Q_i^{*}\, R_Z^{*}\, Q_{si} Q_{fb}^{*}\ , \quad (7)$$

$$Q(A7)= Qe\, Q_i^{*}\, R_Z^{*}\ \ Q_{si} Q_{fb}^{*}\, Qco, \quad (8)$$

Q_{si}^{*}=1-Qsi;

Qco – probability of ignition of the vapor-air mixture cloud.

$$Q(A8)= Qe^{*}\ Qi^{*}\ R_Z^{*}\ \ Qsi\ Qfb^{*}\ Qco \quad (9)$$

$$Q(A9)= Qe^{*}Qi^{*}R_Z^{*}\ \ Qsi\ Qfb^{*}\ Qcd^{*}, \quad (10)$$

Qcd = 1 Qco – probability of combustion of vapor-air mixture cloud, with overpressure development.

$$Q(A10) =Qe^{*}Qi^{*}R_Z^{*}\ \ Qsi\ Qfb^{*}\ Qcd^{*} \quad (11)$$

The probability of depressurization of the installation Qe is determined by the equation Qe=Ne/(N installation T), here Ne is the total number of accidental releases of flammable product at installations of this type (the result of static studies), Nst is the number of observed units of installations, T-period of observation, year.

Analysis of the structure of the formula determining the probability of depressurization of the unit indicates that the result of the analysis has the dimension of 1/year.

All subsequent parameters called "probability" (instantaneous ignition, flaring, dispersion, etc.) have no dimensionality.

Probability of instantaneous ignition of the flowing product Qi=0.05

Probability of flare combustion Of=0.0574.

Probability of fireball Qfb at destruction of the nearby tank under the influence of fire (overpressure) depends on the properties of the product and the possibility of its overheating.

II. Methods

According to the data of Taubkin S.I. [2] and Marshall W. [3], a fireball is formed by instantaneous release of a large mass (at least 10 tons) of liquefied gas or superheated liquid. The degree of liquid superheating should be such that at least 35% of the mass of the combustible substance passes into the vapor state.

Overheating of liquid is possible in a tank, e.g. in case of fire inside the bund only if the tanks are hermetically sealed and have no communication with the atmosphere. If the tanks in the project facility are communicating with the atmosphere, a fire inside the bund will cause the product in the tank to heat up. The temperature of the product rises to boiling point at atmospheric pressure. Further temperature rise of the liquid is not possible because the liquid vaporizes at atmospheric pressure. All heat supplied from outside to the product is spent on vaporization of the liquid. For this case Qfb=0.

Probability R3 of fire prevention due to effective fire prevention measures or weather conditions.

$$R3=Nna/(Ne-Ni), \quad (12)$$

Nna - number of accidents in which no ignition of combustible substances occurred.

Ni - number of cases of instantaneous ignition of the expiring product during its accidental release.

Probability Qsi of ignition of flammable liquid spillage

$$Qsi=Nsi/(Ne-Ni-Nna), \quad (13)$$

Here Nsi is the number of spill ignition events in accidents.

Probability Qco of combustion of a mixture cloud formed as a result of release and subsequent vaporization of combustible substances.

$$Qco=Nco/(Ne-Ni-Nna-Nsi), \quad (14)$$

Here Nco - number of cases of cloud combustion in accidents at the plants of this type. Probability Qcd of combustion of vapor-air mixture with development of overpressure is determined by the formula

$$Qcd=Ncd/(Ne-Ni-Nna-Nsi), \quad (15)$$

Here Ncd is the number of cases of combustion of vapor-air mixture with overpressure development.

If statistical data necessary for calculation of probabilistic parameters included in the formulas are not available, the probability of realization of different accident scenarios is calculated by the formula Q(Ai)=Qe Q(Ai)st, where Q(Ai)st-statistical probability of accident development on the i-th branch of the logical scheme. These data for a release of liquefied petroleum gas (LPG) are determined from Table 1.

Statistical probability of different scenarios of accident development with LPG release (data from GOST R 12.3047-98).

Table 1: *The liquefied petroleum gas data*

Scenario	Probability	Scenario	Probability
Torch	0.0574	Cloud explosion	0.0119
Fireball	0.7039	Hot water dispersion	0.0292
Spill burning	0.0287		
Cloud combustion	0.1689	Total	1

Analysis of the statistical probability distribution of LPG release accident scenarios reveals interesting points:

1. The share of scenarios related to ignition of the combustible substance is too high. Out of all emissions only 3% are dispersed and the remaining 97% are ignited. This situation does not correspond to the actual state of affairs. Analyzing the presented statistics, one comes to the conclusion that it is inexpedient to fight against the possibility of ignition of combustible substances. Why to use explosion-proof equipment, install lightning arresters, install grounding systems, if anyway 97% of cases of release ends up with ignition. Let's imagine a situation when to the frequency of 10-41/year of ignitions will be added another 3%. The result will not change.

2. The proportion of hot water dispersion scenarios assumed at 3% does not correspond to the probability of fire source visibility.

3. GOST gives statistical information on the probability of realization of different scenarios for LPG, but where can we find similar information for flammable liquids and gases?

4. The GOST table assigns a statistical probability of 0.0574 to the flaming accident scenario. This data should be used in the calculation of individual risk depending on the value of the conditional probability of harm to humans from flaring hazards. Where is the method for determining the conditional probability of people being hit by a flare? This technique can only be found in journal articles, but it cannot be used because it does not claim to be "timely".

5. GOST provides 2 scenarios of hot water cloud combustion: simple combustion and combustion with overpressure development. From literature sources we learn that a mixture of methane gas with air cannot explode [4], [5]. What is combustion with pressure development can be understood from FSS 105-03, but what is simple cloud combustion, what are its affecting factors, how does it differ from the fire of a flammable liquid spill? It is known that flammable liquids do not burn, burning vapors above its surface. Perhaps by cloud burning we mean the burning of liquid vapors in a spill fire?

Calculation of individual risk, performed in strict accordance with the methodology of GOST, gives its value with the dimension "1/year". In paragraph 6.7 GOST requires that the calculated risk values comply with the requirements of paragraph 6.2. Clause 6.2 - quote: "Fire safety of technological processes is considered unconditionally fulfilled if:

- Individual risk is less than 10^{-8};
- Social risk is less than 10^{-7};

(Note: The permissible values of individual and social risks are given in dimensionless format!)

The operation of technological processes is unacceptable if the individual risk is greater than 10^{-6} or the social risk is greater than 10^{-5}

What does GOST mean by "individual risk?"

Quote: "individual risk: Probability (frequency) of occurrence of fire and explosion hazards arising from an accident at a certain point in space. Characterizes the distribution of risk"

Clause 6.7 of GOST

1. Requires fulfillment of the conditions of paragraph 6.2, in which they forgot to specify in which point of space the value of individual risk should be determined.

2. It sets the permissible level of individual risk in an uncertain point of space as a dimensionless value, and the calculation method presented in this GOST gives the result with the dimension "1/year". The question arises, how can we compare quantities with different

dimensionality?

3. For comparison, we give the definition of "individual risk" presented in the "Methodological Guidelines for Risk Analysis of Hazardous Production Facilities", quote: "individual risk is the frequency of an individual person being affected as a result of exposure to the studied accident hazard factors". If GOST under the individual risk takes into account the probability (frequency) of occurrence of hazardous factors, then the "Methodological Guidelines" take into account the frequency of human injury. But these are completely different concepts.

The methodology presented in GOST is very similar to a house that forgot to make a roof. It is impossible to live in it!

What should be done when it is necessary to address such materials, because there is no statistical data. Our proposal is that the probability of ignition of an emission is determined by the probability of combustion of a combustible substance with an ignition source. It should be borne in mind that the probability of occurrence of the ignition source depends on the area of the affected object (hot water clouds or liquid liquid spills).

III. Result

Based on a logical partitioning scheme for an accident involving the release of combustibles, it is found that the probability of ignition of a release is determined by the probability of combustible combining with an ignition source.

Abstract

In this article, we will talk about technical risks, their nature of occurrence and their impact on the workflow. Modern technologies are constantly evolving, new devices and equipment are appearing, and the range of influence of computer technology is expanding. Scientific innovations make a huge contribution to the development in all spheres of society, old technical devices are being updated with new, more modern and multifunctional ones. The trend in the development of society, the desire to improve qualitative and quantitative indicators and minimize marriage allow us to speak about the relevance of the chosen topic. The use of modern devices makes it possible to use them more effectively in any field, increasing the parameters that favorably affect the growth of the economy, on which the development of both private companies and the state as a whole depends.

Keywords: technical risks, innovative technologies, computer technologies, digitalization, innovative risks

Innovative technologies play a big role in the modern world. The use of machine labor and computers can replace human labor in many industries, both physical and mental. The desire to improve performance and minimize risks forces manufacturers to purchase new equipment capable of performing a much larger list of functions than the previous one. Many different scientific papers have been carried out on this topic, thousands of studies have been conducted taking into account the effectiveness of the introduction of innovative technologies, which allows us to talk about the right approach in this direction.

So, technical risk is the probability of an event causing system malfunctions related to equipment malfunction, failures in technical infrastructure, reduced productivity, etc. Technical risks negatively affect the economic development of the company, its image, the quality of products, and also cause delays in the timing of orders.

There are many types of technical risks in the production and sale of products, we will discuss the most likely of them:

- Engineering errors. When planning a project, it is necessary to take into account many significant factors that affect both the performance of equipment and its high-quality performance. All these responsibilities fall on the shoulders of engineers, whose mistakes can significantly reduce the overall performance of the entire company.
- Defects in raw materials. This factor does not depend on the company that manufactures and sells products, but on the delivery company. The delivery of low–quality goods, the presence of defects in blanks, delays for various reasons - all this affects the number of products produced, compliance with deadlines and the image of the company as a whole.
- Manufacturing errors. When manufacturing goods, it is necessary to strictly follow the instructions, comply with safety requirements when working with hazardous production facilities and use the equipment for its intended purpose. To do this, it is necessary to competently

hire staff and train them to work with new devices that have not previously been used in the course of their activities.

• Sales of products. Most companies that produce products offer services for delivering goods to the buyer. There are two ways to hire employees yourself or use the delivery services of transport companies. For the first option, it is necessary to consider the terms of delivery so that during transportation the products are not damaged and spoiled, delivered to the buyer ready-made. The second option involves cooperation with other entrepreneurs or companies, when concluding a contract with which it is necessary to take into account the experience of its representatives, transportation conditions, well-chosen personnel and many other factors affecting the delivery of manufactured goods to the consumer.

There are many factors that negatively affect technical risks, let's talk about the main ones:

- Low level of scientific research. This type belongs to the criteria of production safety. The scientific technologies used do not meet the proper level of safety, which leads to negative consequences.
- Low level of development work. The choice of potentially dangerous design schemes and principles of operation of technical systems, errors in determining operational loads, incorrect choice of structural materials, insufficient margin of safety, lack of technical safety equipment in projects – all this increases the level of technical risks of production.
- Pilot production of new equipment. The use of outdated equipment or low-quality devices that have not been properly tested. Maintaining documentation of safety criteria and compliance with all requirements is also an important aspect of maintaining production.
- Serial production of unsafe equipment. A violation in the chemical composition of the products produced, inaccuracy in the proportions of the components used, inconsistency of the specified dimensions of the finished product, errors in choosing the temperature during production, violation of the instructions in the sequence of actions performed – all this leads to increased technical risks and reduced work efficiency.
- Violation of the rules of safe operation of technical systems. When using the equipment, it is necessary to observe all prescribed precautions – use the devices only in cases specified by the manufacturer, observe operating modes, do not overload or overheat the equipment, carry out professional repairs of damaged equipment and check its operability in a timely manner, adhere to safety measures during transportation and use of equipment, etc.
- Staff mistakes. Perhaps one of the most important reasons for the occurrence of technical risks is the incompetence of the people working behind the entrusted equipment. It is necessary to constantly improve the skills of personnel, conduct discourses and educational programs, and train them to work with new devices. Important are the personal qualities of workers – discipline, responsibility, stress tolerance, the ability to make quick right decisions in case of emergency situations, etc. It is necessary to pay due attention when applying for a position, take into account previous experience and characteristics from previous work.

In the context of digitalization of society, these problems can be solved using computer technologies used in the development and modeling of projects, improving and optimizing equipment, training personnel through video lectures, signing cooperation agreements and purchasing goods with other companies, placing orders through online resources and much more.

However, with the introduction of scientific technologies, a new problem appears – innovative risks, indicating the likelihood of losses when introducing innovative technologies. In other words, innovation risk is the consequences that an enterprise may face when introducing innovative technologies.

There are several types of innovative risks that can lead to a deterioration in the quality and quantity of manufactured products, here are some of them:

- Lack of financial resources. Lack of financing to achieve the company's goals – purchase of new raw materials, purchase of new modern equipment, maintenance and repair of damaged devices, and many other factors that cause lag and contribute to downtime in production.

- Underestimating marketing when planning a project. This type of risk may arise due to improper use of the budget, in which there will not be enough funds for good advertising of goods, which will lead to a large difference between the products produced and sold, will entail stagnation in production, and, as a result, losses to the company.
- Changing consumer needs and demands. The changing structure of the modern market significantly complicates the choice of manufactured products from the manufacturer, because the demand for the supplied goods can significantly decrease. The solution to this problem can be a constant analysis of supply and demand in the market, and in case of its decline, the opportunity to change the direction of production to other, more relevant and purchased goods.
- Lack of raw materials and materials used. With the introduction of new technologies, the production process changes significantly, especially in cases where completely new products are produced. To do this, it is necessary to correctly assess the available budget and use it to the maximum benefit. The manufacturer should think in advance about the suppliers from whom he will purchase materials, calculate how much and what kind of raw materials are needed for this type of product in order to avoid a shortage of one raw material and an excess of another.
- Data leakage within the company. The production of new products, especially new ones for the existing market, should always remain secret until the moment of product sale. In order to avoid disclosure of information, it is necessary to clearly identify the circle of people who may know about the planned deliveries. Otherwise, competitors are able to steal the idea and launch this industry into mass consumption faster, which can significantly reduce projected sales revenues and lead to losses for the company.
- Copyright of scientific technologies. When using new directions, it is necessary to make sure that these innovations do not have copyright. Otherwise, the owner may demand a percentage of the profit received, which will bring huge losses to the company.
- Delays in production dates. In fact, this species combines the first and fourth species mentioned above. All these factors negatively affect the entire production process, from the purchase of goods and creation to the delivery of the finished product to consumers. This can lead to delays and downtime, loss of clientele and investors, and loan arrears if creditors' money was used during the sale.

There are innovative risks at each stage of production – at the stage of project planning, purchasing new equipment and updating old equipment, using purchased equipment.

Consider the sources of innovation risk:

– financial (arise as a result of improper management of financial flows). They are divided into portfolio (the impact of macroeconomic indicators on the assets of enterprises), currency (changes in the exchange rate) and interest (changes in interest rates in the case of borrowing funds);

– insurance (related to the possibility of insured events);

– marketing (low-quality marketing research);

– commercial (losses arising in the process of selling goods or services, or in case of loss of profit);

– industrial (disruption of production from equipment failure to destruction of buildings);

– investment (the possibility of non-repayment of invested funds);

– political (the possibility of changing the socio-political situation);

– environmental (the likely onset of environmental degradation, which led to a deterioration in the quality of forest, water, land, air conditions, as well as a change in the life and health of third parties).

Based on the opinion of the author, E.G.Zakharenko identified such risks as:

1) external, risk-related effects of direct (suppliers, competitors, consumers, investors) and indirect (politics, economics, social sphere, ecology, force majeure) impacts on project performance;

2) internal, including resource and organizational-production (management and risks of interaction within project teams).

Innovation risks are closely related to economic risks. The main economic risks in the Russian Federation today include:

– the federal budget deficit;

– decrease in the volume of the reserve fund;

– a noticeable increase in the unemployment rate;

– decrease in the inflow of foreign investments into the Russian economy and the outflow of Russian investments abroad;

– a sharp drop in the exchange rate of the Russian ruble and the stock market caused by external factors.

Project risk analysis is an important part of the innovation planning process. It occupies one of the leading places along with goal setting, budget development, and approval of the project plan.

Of course, in order to avoid financial losses, it is necessary to try to reduce innovation risks. Here are some of the ways to minimize them:

– avoidance – rejection of projects with a high level of risk (this is typical for risk-averse investors who do not expect a high level of income from financial investments);

– localization – concentration of high-risk activities within one structural unit or territory (such a policy will protect other units from the consequences of the occurrence of a risky event);

– dissipation – distribution of risk in time and space;

– diversification – working in several markets, in different fields of activity, with different partners;

– reservation (formation of a reserve fund in case of failures in financing or losses during the implementation of an innovation);

– insurance (using the services of third–party insurance companies and choosing the most optimal insurance system) - risk distribution between performers and projects;

– diversification (dispersion) of risks for unrelated projects;

– hedging (reducing the risk of adverse (as a result of market factors) changes in the price or expected cash flow of one instrument by using another instrument associated with it as part of the project);

– limitation (introduction of a limit on expected project costs);

– transfer of risk to another person in case of exceeding the maximum acceptable value for the enterprise.

In order to avoid significant financial losses, insurance is used that can compensate for part of the losses incurred as a result of production. With the help of insurance, it becomes possible:

- To compensate for losses or lost profits. With an increase in the number of negative risk factors, the insurance company can return to the entrepreneur part of the funds spent on compensation for losses, which will help the production to survive the crisis more easily.
- Coverage of damage from possible negative events. This aspect refers to events that can lead to damage to property, equipment, finished products and other forms of ownership, compensation for the loss of which the insurance company is able to reimburse.
- Compensation for damage caused by a third party. In cases where the actions of other persons, both individuals and legal entities, have led to losses of the company, the insurance company can reimburse all losses of the organization.
- Compensation for investment losses. In the case when new technologies not only did not benefit, but also led to losses of the organization, the insurance company will help to recover the costs.

As we have already understood, insurance companies help entrepreneurs to use innovative technologies more safely when doing business, covering part of the costs in case of unsuccessful attempts at reorganization. This leads to an increase in the number of new developments in this area, increasing the economic development not only of an individual enterprise, but also of the state economy as a whole. It is necessary to develop this institution, help firms use all available resources to achieve new goals, develop in the chosen direction and develop the state economy through trade both within one country and on the world market.

It is necessary to mention one more concept – competitiveness – the ability of an enterprise to compete adequately with other similar firms and develop effectively in a market economy. This quality expresses the ability of an organization to change the direction of its activities depending on customer demand, anticipate possible risks and avoid them with minimal consequences for its budget. There are many factors – the field of activity, consumer demand and opportunities, mainly financial, the willingness of managers to global changes, etc.

Obviously, manufacturers are not able to see the future in order to know at what point production may come to a standstill. However, it is necessary to have a backup plan, especially typical for unstable market relations, with which you can not only avoid a production crisis, but also reach a new level of company development, deferred funds that can be used to change the course of business without drastic losses.

The state is interested in supporting private business and protecting it from potential risks, so there are various programs to identify the most vulnerable places in production planning. For example, the St. Petersburg University of Information Technologies of Mechanics and Optics has created a risk register that allows you to record and track all factors affecting innovation risks. This mechanism is used at all stages – project development, organization of supplies and purchases of raw materials and equipment, manufacture of goods, etc., contains all the basic data about risks, their changes, possible consequences, people responsible for working in different directions, as well as ways to prevent and minimize consequences.

In particular, this educational institution has developed an Information Management Decision-Making System that allows you to keep a risk register and assess its importance, conduct test activities for new employees who want to get a job at the enterprise, take into account their professional qualities and much more. As mentioned earlier, well–chosen staff is a reliable way to protect against many factors of existing risks.

Based on the conducted research, it can be noted that most innovation risks are associated with limited financial resources. In the course of activity, the costs for each stage of production formation often exceed the expected ones, new areas appear for which funds need to be allocated, prices rise due to inflation, etc. Recently, the number of companies aimed at creating and selling products has increased, but the quality of the goods produced is not always the best.

Everything is complicated by the budget of the organization – miscalculations in the purchase of goods lead to the purchase of cheap but lower–quality raw materials, lack of funds for equipment - the use of old, less efficient devices and many others. All this leads to the appearance of cheaper, but less high-quality products.

Summing up the above, I would like to remind you once again about the existing technical risks. As mentioned earlier, it is impossible to predict at what stage of the company's development losses will appear, but they can be prevented and minimized.

In this article, we discussed the most possible factors that negatively affect the development of production facilities, which can cause significant losses to the efficiency and image of the company. In addition, we have studied the nature of their occurrence, the main causes of their occurrence and ways to eliminate them.

The use of information technologies, on the one hand, makes it possible to avoid technical risks by optimizing production, improving equipment, replacing human labor, using risk registers, etc., but on the other hand, they carry new problems, the use of which does not guarantee an absolute result.

Another important factor that I would like to mention again is the search for qualified and responsible employees who are able not only to do their job competently, but also to be prepared for emergency situations. It is necessary to constantly improve the level of knowledge of the team – to conduct educational courses on working with equipment, to remind them about compliance with safety regulations at work, to send them to study courses, to apply mentoring, etc.

By observing all the above rules and hiring competent analysts who are able to constantly monitor changes in market demand, an entrepreneur will be able to protect himself and his company from many factors that negatively affect the improvement of his company, effectively develop his company and the economy of the state as a whole.

Abstract

Research on navigation of mobile robots in uncertain dynamic environments is of great importance. This article is focused on solving existing problems such as planning, optimization, failure in difficult situations, and error rate vector prediction under constantly changing uncertain conditions. The aim of the conducted research is to propose a multilayer fuzzy logic model based on decision making for robots to find safe path navigation by overcoming any kind of obstacles and to understand collision-free movement of mobile robots in an uncertain dynamic environment. In this study, fuzzy logic control prediction and multilayer solution priority rules are used to improve the quality of the next position based on the path length, safety and realization time. For this purpose, the article considers the topic of calculating the risk of collision with obstacles for planning the trajectory of a mobile robot with a fuzzy controller in an environment with dynamic obstacles.

Keywords: dynamic mobile robot, fuzzy approach, dynamic obstacle, membership function, risk assessment, fuzzy inference.

I. Introduction

In modern times, there is a great interest in robotic devices in all fields of industry, computer systems, scientific research centers, service works, household and agriculture. That is, they are considered necessary and an important factor in all fields. The replacement of humans in dangerous and military operations by robots has led to an increase in researchers' interest in mobile intelligent robots [1]. It is very important for mobile robots to plan the trajectory of an optimal free path by overcoming obstacles from their starting point to the final target point based on indicators such as time, distance and energy [2]. The goal of mobile robot is to understand the environment, interpret received data, improve knowledge about its position, overcome obstacles by controlling the turning angle and linear speed of the mobile robot, and to plan the route from the starting point to the final position [3]. Path planning in static environments is a well-studied and efficiently solved problem. However, the problem of robot trajectory planning in an environment presence several dynamic obstacles is still has not been solved. This is due to the need to add time dimension in trajectory planning [4].

Classical approaches to planning mobile robots are inadequate. Such approaches cannot overcome the challenges of dynamic environments or inadequate information about the environment [5,6]. Therefore, some reactive (i.e., taking action after the occurrence of events not taken into account in advance) approaches are presented. The application of these approaches allows to learn, justify the main task and use artificial intelligence methods in solving problems. In this work, artificial intelligence methods, including fuzzy logic and neural networks are form the basis of navigation systems in mobile robots [7-9]. Fuzzy logic (FL) is a type of artificial intelligence that describes human thoughts and decision-making. Fuzzy logic allows interpretation of intermediate values between traditional values, such as yes/no, true/false, high/low and etc.. Fuzzy logic approaches have been used in many studies on mobile robot navigation [10].

A number of approaches have been proposed in various research studies related to the pre-planning and analysis of the robot's motion trajectory. Comparing the approaches proposed in this study with other intellectual and heuristic methods is an effective way to solve the previously mentioned problems and make effective decisions in complex situations. Especially, the combination of our approach with fuzzy logic is one of the most important types of intelligent hybrid systems. In the fuzzy logic control system, the priority and prediction rules of the multilayer decision-making approach are used to improve the quality of the next position related to the working time, the safety conditions in risky situations, and the trajectory. Fuzzy systems are still used because planning is still difficult when there are some dynamic obstacles. This is because planning is included as an additional dimension to the search space explored by the planner. Moving obstacles and their velocity vectors are not known in advance. Other approaches to planning mobile robots are not powerful enough and cannot overcome the challenges of mixed complex situations where the environment is dynamic and unknown.

In this research work, a multilayer decision-based fuzzy logic approach is proposed for obstacle avoidance based on velocity vector of dynamic obstacle and priority behavior. Planning the navigation of a mobile robot in a complex dynamic environment and performing sensor-based planning tasks are the essence of this approach. To make the proposed approach more efficient and intelligent, it is considered appropriate to use fuzzy logic controllers. These controllers evaluate the robot's next-state prediction procedure in the action area and enable optimal decision-making. The best next step of a mobile robot is selected based on several proposed criteria for solving sensor-based planning problems in both risky and complex dynamic uncertain environments. These criteria are prepared by the rules of the proposed approach and transformed into fuzzy variables to create a fuzzy reasoning system.

II. Mathematical modeling and kinematics of a mobile robot

Mathematical modeling of a mobile robot in a environment with dynamic obstacle includes a risk calculation based on finding the distance between the robot's platform and the nearest obstacle to the left, front, or right at each program iteration. The distance to the nearest obstacle is determined by a measuring sensor placed on the platform of the mobile robot.

Figure 1 provides a graphical representation of the distances between the platform of the mobile robot and the obstacles.

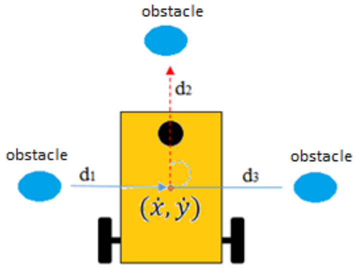

Figure 1: *Distances between the platform of the mobile robot and the obstacles*

In the computer modeling of the mobile robot, dynamic moving obstacles whose position in its working zone is unknown were considered. The result of the measurements performed by distance measuring sensors in their Cartesian coordinate system is known at each program iteration. The modeling involves the problem of measuring the distance between all transmitters of the mobile robot and dynamic obstacles with unknown position during each program iteration. The distance between the mobile robot and obstacles is determined by the formula (1) [1,2]:

$$d_{Si} = \sqrt{(x_m - x_{Si})^2 + (y_m - y_{Si})^2} \quad (1)$$

there are (x_m,y_m) – coordinates of the obstacle; (x_{Si},y_{Si}) - are the coordinates of the i^{th} measuring sensor. If the obstacle is the left dynamic obstacle (or right , or front dynamic obstacle), (figure 2), the distance between the measurement sensor and the obstacle is calculated as follows:

$$d_{Si} = \sqrt{(x_{ci} - x_{Si})^2 + (y_{ci} - y_{Si})^2} \text{ , } i = \overline{1,3} \quad (2)$$

There is (x_{ci}, y_{ci}) – are presented as the coordinates of the nearest point indicating the distance from the i^{th} measurement sensor to the obstacle (Fig. 2).

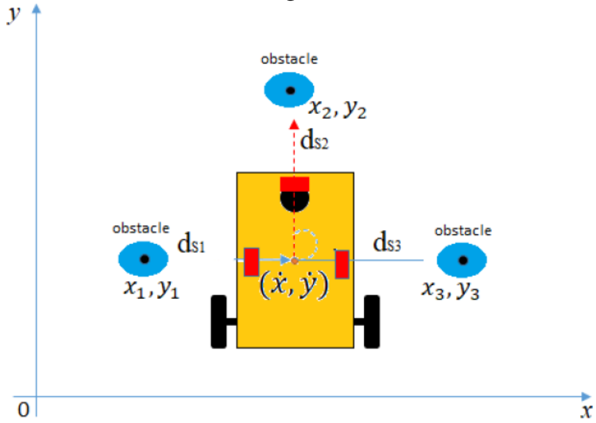

Figure 2: *Graphical representation of the distance between a mobile robot and a dynamic obstacle*

In practical terms, employing geometric techniques for distance measurement via sensors is not deemed significant. Currently, dynamic obstacles with unspecified positions may have varied shapes and placements. The sensor covering mounted on the mobile robot's working body is positioned to establish contact with obstacles.

The placement density of the measurement sensors should be arranged in such a way that the invariable (i.e., static state) zones of the sensor cover are not taken into account [7].

During the calculation of the distance between the mobile robot's platform and nearby obstacles, any objects within the sensing range of the distance sensors on the platform are considered obstacles. In computer modeling, the information (input data) received from all sensors represents the input parameters of the function. Based on the input data, the distance between each sensor and the nearest dynamic obstacle is determined.

In the process of developing the intelligent planning system of real-time displacement of a mobile robot in an uncertain environment, it is necessary to take into account a number of its characteristics, for example, the size and maximum speed of the platform of the mobile robot, the discretization period, the type of mechanical connection between the motor and the wheels.

There are two typical configurations of a mobile robot: a differential and a classic three-wheeled mobile robot (Figure 3) [8].

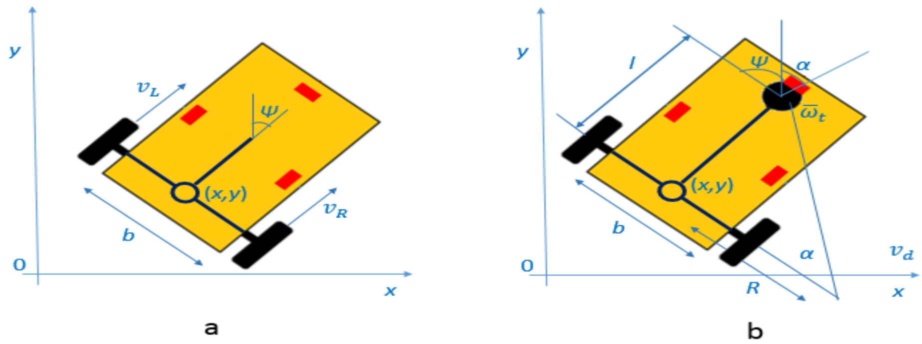

Figure 3: *a) differential və b) a classic three-wheeled mobile robot configurations*

The differential configuration of the mobile robot uses independent velocities on both wheels (left and right wheels, VL and VR) to move it to a specific point (x, y) in a two-dimensional plane and in a specific direction Ψ.

The displacement of the three-wheeled mobile robot towards a target point and its direction are determined by utilizing a single controlled speed and angle applied to one wheel. The research focuses on a differential mobile robot as the subject of investigation.

In the differential mobile robot model, ωL and ωR represent the angular velocities of the left and right wheels. The radius of the driven wheels is denoted by r, and the distance between the two wheels is denoted by b. Assume that solid objects placed on the platform of a mobile robot move on a non-deformable horizontal surface. At any moment, the current coordinate (x, y) and rotation angle (ψ) of the mobile robot in the Cartesian system are known (Fig. 3).

The movement parameters of the mobile robot in the working area are calculated by the following formulas [1,5]:

$$q = [x \;\; y \;\; \psi \;\; \Phi_L \;\; \Phi_R\,]^T \tag{3}$$

$$\begin{bmatrix} \dot{x} \\ \dot{y} \\ \dot{\psi} \end{bmatrix} = \begin{bmatrix} \text{-}sin\,\psi & 0 \\ \text{-}cos\,\psi & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} V \\ \omega \end{bmatrix} \tag{4}$$

Here: x, y – the current coordinates of the mobile robot.φ_L- rotation angle of left wheel;

φ_R- rotation angle of right wheel;

ψ – turn angle of the mobile robot.

The corresponding linear and angular velocities of the mobile robot are defined as:

If we replace statements (5), (6), (7) with (4):

The current coordinate and rotation angle of the mobile robot – (x, y) and Φ are determined from the following equation [9]:

$$V = \frac{V_R+V_L}{2} = \frac{\omega_R+\omega_L}{2} r \tag{5}$$

$$\omega_L = \frac{d\Phi_L}{dt} = \frac{V-(b/2)\omega}{r} \tag{6}$$

$$\omega_R = \frac{d\Phi_R}{dt} = \frac{V+(b/2)\omega}{r} \tag{7}$$

$$\begin{bmatrix} \dot{x} \\ \dot{y} \\ \dot{\psi} \end{bmatrix} = \begin{bmatrix} \text{-}rsin\,\psi/2 & \text{-}rsin\,\psi/2 \\ \text{-}rcos\,\psi/2 & \text{-}rcos\,\psi/2 \\ \text{-}r/b & r/b \end{bmatrix} \begin{bmatrix} \omega_L \\ \omega_R \end{bmatrix} \tag{8}$$

Based on the obtained equation (9), the current coordinate and direction of the mobile robot over time is calculated as follows [9,10]:

$$\dot{x} = \frac{r\cos\Psi(\omega_R+\omega_L)}{2}$$
$$\dot{y} = \frac{r\sin\Psi(\omega_R+\omega_L)}{2} \qquad (9)$$
$$\dot{\Psi} = \frac{\omega_R-\omega_L}{b}r$$

here, Ψ_{Li} – relative rotation angle of the left wheel;

Ψ_{Ri} – relative rotation angle of the right wheel.

By determining the displacement of the wheels of the mobile robot, the calculation of its current coordinate is performed taking into account the already known position of the robot. The relative rotation angle of each wheel is measured by means of position sensors placed on the axles of the electric motors.

$$\begin{cases} x_i = x_{i-1} + \frac{r\cos\Phi(\Delta\Phi_{Ri}+\Delta\Phi_{Li})}{2} \\ y_i = y_{i-1} + \frac{r\sin\Phi(\Delta\Phi_{Ri}+\Delta\Phi_{Li})}{2} \\ \Phi_i = \Phi_{i-1} + \frac{r(\Delta\Phi_{Ri}+\Delta\Phi_{Li})}{b} \end{cases} \qquad (10)$$

Equation (10) shows that the movement coordinates and direction of the mobile robot depend on the measurement accuracy and geometrical parameters (the radius of the wheel–r, distance between the two wheels –b) of the rotation angle of the wheels.

Table 1 lists the values of the parameters of the studied robot model.

Table 1: *Mobile robot parametrs*

Parameters	Values
The mobile robot's platform size, m	0.50
Distance between drive wheels -b, m	0.40
The radius of the wheel -r, m	0.042
Engine type	12V DC
Maximum engine speed, dövr/dəq	120
Discretization period, s	0.028

Based on the data in Table 1, the values of the following parameters of the mobile robot can be calculated:

- number of iterations per second: $\frac{1}{0{,}028} = 36$
- the maximum displacement step of a wheel in each iteration:

$$\frac{100*2\pi*0{,}042}{60*36} = 0{,}0122 \text{ m.}$$

Finding a suitable collision-free path connecting the initial position p0 at the initial time t0 of the mobile robot with the final position pend at the time tend can be considered as a navigation problem (task). In the environment with dynamic obstacles, it is important to determine the velocity vector of each obstacle, especially the displacement of obstacles in different directions towards the moving robot, the number of iterations in one second and the maximum displacement step of one wheel in each iteration.

The main problem here occurs when the robot decides to move inside the dangerous area where 3 obstacles moving in an unknown direction move towards each other and collide with the next position. Since the robot has a different solution to avoid obstacles in each movement, it cannot choose how to avoid them. For example, the decision made by the robot to avoid an obstacle moving to the right is to move to the left, but the decision made by the robot against obstacles moving to the left and forward direction is different from this decision [11]. Therefore, a collision will occur as long as the robot cannot predict the dangerous area, i.e. predict and change its state to another state with a lower risk of collision and obstruction. In order to solve the problem, the development and realization of the intelligent planning system of the predicted navigation of the mobile robot in an unknown dynamic environment was considered.

The main goal in this section is to guide a robot moving under uncertainty to choose the most optimal next step between positions without collision with dynamic obstacles. A fuzzy control system is developed to verify the forecasting process and decisions about the next position and to choose the best positions in terms of minimum risk. This control is activated after the next step finds a position away from the collision. The values of three fuzzy variables, including left dynamic (LeftD), front dynamic (FD), and right dynamic (RightD), are calculated by the control for each iteration.

The first fuzzy variable (FV) is the distance to the left (right or front) dynamic obstacle, defined as intersection points (IP) between the sensor range and the obstacle. The robot learns to determine the safe distance to the left (right or front) dynamic obstacle when detected through this part of the control. The control measures the intersection points between the sensor layers and the obstacle. If the obstacle intersects the top layer of the sensor, it means that the obstacle is far from the robot. At the same time, if the obstacle crosses the middle layer of the sensor, it indicates that the distance between the obstacle and the robot is safe. However, if the intersection occurs with a lower layer, the robot is close to the obstacle. By extracting these values, we obtain the values (FV) to be used in future fuzzy control. This variable can be formulated as follows [11]:

$$Sensor\ layers\ (R_i = 0.2, 0.4, 0.6, 0.8), Range\ quarters\ (q_j = 1, 2, 3, 4^{th}) \quad (11)$$

$$IP = (n, R_x(q_j, :), R_Y(q_j, :), x_{polygon}, y_{polygon}) \quad (12)$$

Function [distance] = to obtain the obstacle distance from the interval (cross-interval, first layer radius, second layer radius, third layer radius, fourth layer radius) (13)

$$Function\ (distance) = Determining\ the\ direction\ of\ the\ obstacle\ from\ q_j$$

$$(1^{st} q_j,\ 2^{nd}\ q_j) \quad (14)$$

$$LeftD\ (R_i, q_j) = (distance, direction) \quad (15)$$

$$LeftD \in [-1, 1] \quad (16)$$

When the minimum distance of LeftD is placed at the new position Ri(min), its maximum distance occurs at R_i(max). All values of LeftD are between these maximum and minimum levels. A zero value of IP indicates that the obstacle is outside the range of the sensor, and a positive value indicates that the obstacle is within the range of the sensor. Three ranging sensors are used to determine the exact position and direction of obstacles. For example, if the robot detects that the obstacle is in the first and second quarters, it means that the obstacle is in front of the robot. The second and third quadrants show the left side of the robot, and the third and fourth quadrants show the obstacles behind the robot. Finally, the fourth and first quadrants belong to the right side of the robot. Sometimes the obstacle is in the first quarter of the navigation. In this case, the sensor informs for all other quarters that the obstacle is in the right corner of the robot, and so on. Four linguistic variables were identified for LeftD, including Close, Medium, Far, and Very Far. Analogously, these linguistic variables were used for the right and front dynamic barriers.

Input parameters Left, FD, and Right, entered as control parameters, represent the distance to the left, right, and front dynamic obstacles, respectively. These elements are determined using the same equations applied for dynamic barriers.

The constituent functions of the left dynamic (LeftD), front dynamic (FD) and right dynamic (RightD) input variables are the same, and their structure is shown in Figure 4. Fuzzy subsets for the input and output variables of the mobile robot are defined as trapezoidal membership functions.

Upon detecting the obstacle's distance to the next position and its location, the controller organizes these obstacles into a matrix. dynamic obstacles. If the controller detects that the next position faces two or more dynamic obstacles, it determines the position of the three nearest dynamic obstacles.

The output fuzzy variable of this process is the risk for the next trajectory. Fuzzy rules are formulated to evaluate the efficiency of the next trajectory. An intelligent system has been developed with five linguistic grades for this speech, including Very High (VH), High (H), Normal (N), Low (L) and Very Low (VL). The output variable of the proposed fuzzy control can be expressed as:

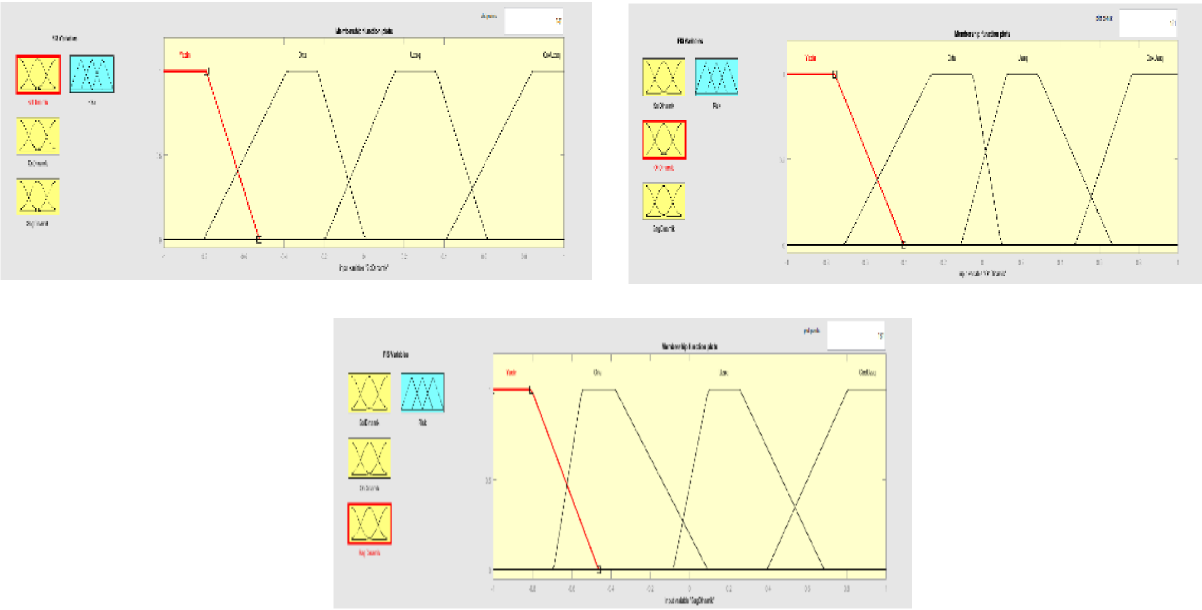

Figure 4: *Obstacle function curves using the trapezoidal method*

$$Risk = Function\ (LeftD, FrontD, RightD),\ \ Risk \in [0, 1] \tag{17}$$

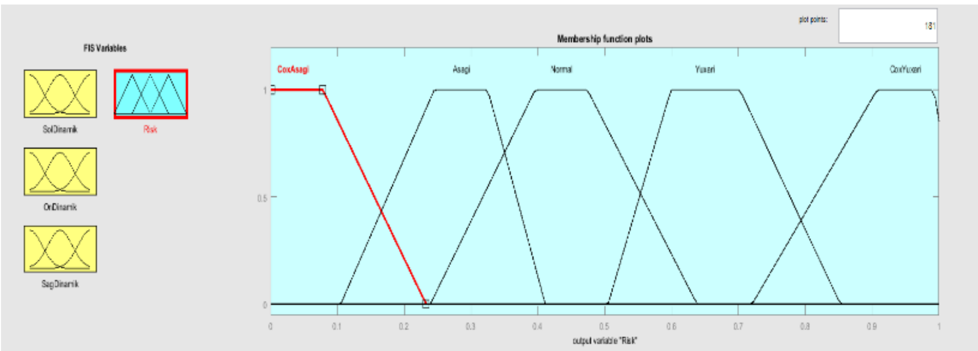

Figure 5: *Trapezoidal membership function curves of risk*

III. Structure of the issue

Trapezoidal membership functions (MF) are chosen in fuzzy logic depending on the structure of the issue:

1. Have simpler analytical structures.
2. Preserves the adaptability.
3. It gives the user more freedom in MF construction.
4. Preserves the novelty.

Also, 5 intervals are selected to evaluate the efficiency of the next trajectory by accurately identifying dangerous situations and to formulate fuzzy rules.

Determining the input and output values of the mobile robot. Designed fuzzy logic elements.

İnput variables:

Left dynamic = relationship between the robot and the left dynamic obstacle in the interval -1÷ 1.

Front dynamic = -1÷ 1 relationship between the robot and the front dynamic obstacle in the interval -1÷ 1.

Right dynamic = relationship between the robot and the right dynamic obstacle in the interval -1÷ 1.

Output variable:

Risk = Probability of collision risk of robot with obstacles in interval 0÷1.

The goal is to guide the robot to choose the most optimal next step between positions, avoiding collisions. Fuzzy management is developed to verify the forecasting process and next position decisions and select better positions with minimum risk. This control is activated after the next step finds a position away from the collision. The values of three fuzzy variables, including left speaker, front speaker, and right speaker, are calculated by the control for each iteration. Tables 2 and 3 describe the normalized universe values of the input and output parameters.

Table 2: *Normalization table of universes of input parameters*

İnput parameters	Range	Normalized piece	Linguistic variable
Left, front, right dynamic obstacles	[-∞ ÷ -1.00]	[0 ÷ 0.25]	Close
	[-0.99÷0.00]	[0.25÷0.5]	Medium
	[0.01÷0.50]	[0.5÷0.75]	Far
	[0.51÷1.00]	[0.75÷ 1.0]	Very far

Table 3: *Normalized universium table of the output parameter*

Output parameters	Range	Normalized piece	Linguistic variable
Risk	[0÷0.20]	[0÷0.20]	Very low
	[0.21÷0.40]	[0.21÷0.40]	Low
	[0.41÷0.60]	[0.41÷0.60]	Normal
	[0.61÷0.80]	[0.61÷0.80]	High
	[0.81÷1.00]	[0.81÷1.00]	Very high

Defining fuzzy rules. The knowledge base consists of a set of fuzzy control rules expressed as a fuzzy conditional proposition. The knowledge base constitutes the rule set of the fuzzy controller. When building a knowledge base, it is important to define input variables, output variables, types of fuzzy regulation rules etc. Fuzzy rules must be based on one of four basic conditions to obtain. For example, 1) if the fuzzy control rules are given in the form of a fuzzy conditional sentence, then there is a connection between the state variables included in the condition part and the control variables included in the sentence part; 2) in the case of fuzzy rules, the management activity of a person is observed and created by revealing the input-output connection; c) in the linguistic approach, the fuzzy model of the controlled process can be viewed as a linguistic description of its dynamic characteristics. d) the knowledge base of the fuzzy controller is formed through self-learning.

The fuzzy IF-THEN implication proposed by Mamdani was used in the research work. Each fuzzy control rule is given in the form of a fuzzy conditional sentence. These rules describe the relationship between the state variables included in the condition part and the control variables given in the judgment part. 64 fuzzy rules indicating the positions of the left, front and right dynamic obstacles and the dependence of the risk on these positions have been defined. (Figure 6).

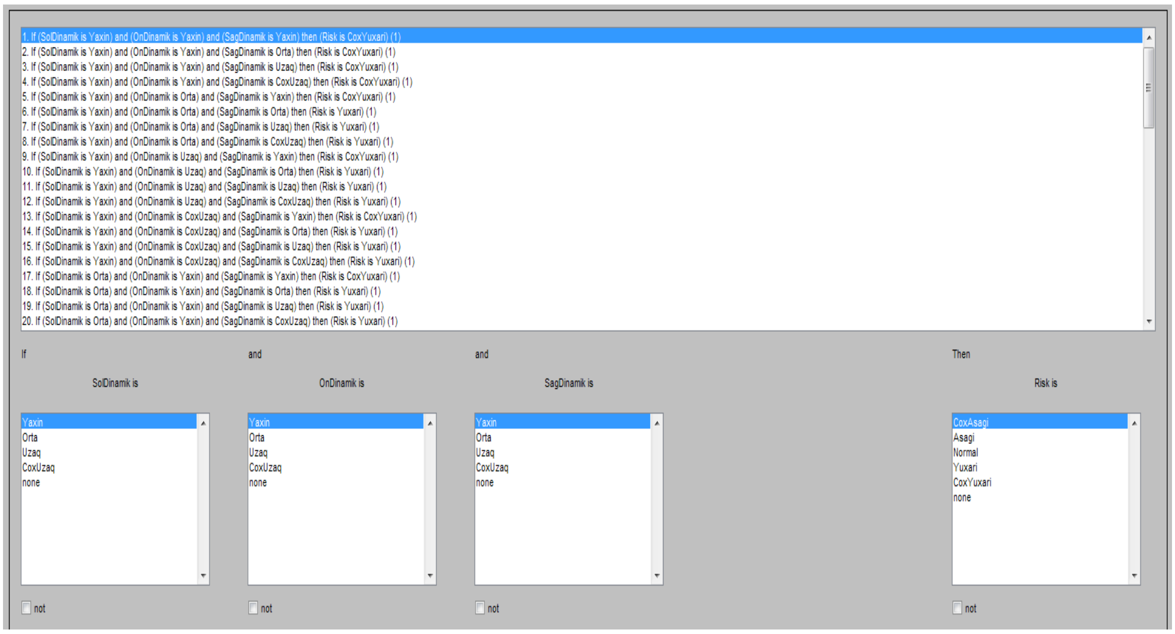

Figure 6: *Fuzzy-logic rules*

There is some examples:

Rule 1.

If (LeftDynamic is Close) and (FrontDynamic is Close) and (RightDynamic is Medium) then (Risk is VeryHigh)

If (LeftDynamic = -0.83) and (FrontDynamic = -0.77) and (RightDynamic = -0.26) then (Risk = 0.89)

Rule 2.

If (LeftDynamic is Close) and (FrontDynamic is Medium) and (RightDynamic is Far) then (Risk is High

If (LeftDynamic = -0.81) and (FrontDynamic = -0.32) and (RightDynamic = 0.07) then (Risk = 0.67)

Rule 3.

If (LeftDynamic is Medium) and (FrontDynamic is Medium) and (RightDynamic is Far) then (Risk is Normal)

If (LeftDynamic = -0.30) and (FrontDynamic = -0.32) and (RightDynamic = 0.25) then (Risk = 0.44)

Rule 4.

If (LeftDynamic is Far) and (FrontDynamic is VeryFar) and (RightDynamic is Far) then (Risk is Low)
If (LeftDynamic =0.44) and (FrontDynamic = 0.94) and (RightDynamic =0.24) then (Risk = 0.26)
Rule 5.
If (LeftDynamic is Medium) and (FrontDynamic is VeryFar) and (RightDynamic is VeryFar) then (Risk is VeryLow)
If (LeftDynamic = -0.28) and (FrontDynamic = 0.82) and (RightDynamic = 0.95) then (Risk = 0.082)

Figure 7 illustrates the logic inference system.

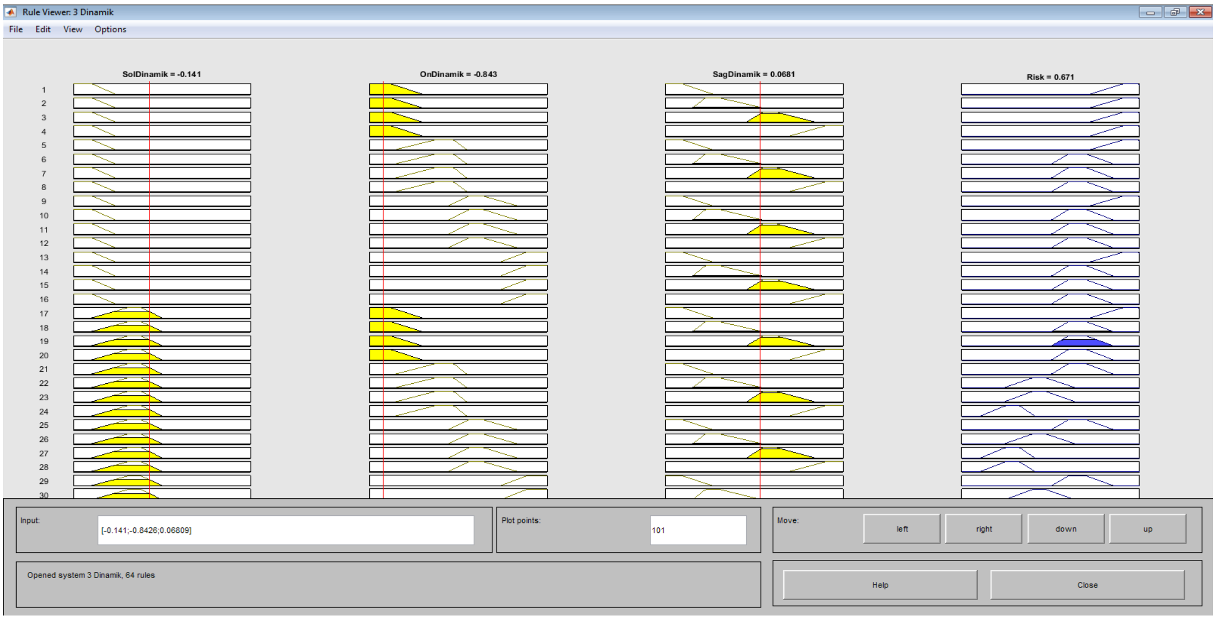

Figure 7: *Logic inference system.*

Figure 8 depicts the fuzzy spatial clusters of the mobile robot's left, front and right dynamic obstacles.

IV. Conclusion

A sensor-based algorithm is proposed for robot trajectory planning in various dynamic environments. A fuzzy system was used to evaluate the positions generated by the planner and select better steps that reduce the total path length with the help of an algorithm. In addition, it keeps the robot away from possible local minima. This system uses priority rules and prediction of a multilayer approach to improve the quality of the next position by taking into account risky situations to develop three fuzzy control variables. Fuzzy variables will be calculated every time the planner creates a new collision configuration. They will serve as input to a fuzzy reasoning system to decide the overall risk of the next step. When the prediction shows that the risk of collision with many obstacles is too high, the mobile robot finds a new way from alternative solutions to avoid the risky regions through priority behavior. This algorithm makes the multilayer decision making process more efficient and effective by using the advantages of fuzzy logic.

Abstract

The article studies the features of managing various types of risks. The main elements of risk management relevant for managing economic clusters are identified. The article studies the features of managing various types of risks. The main elements of risk management relevant for controlling of economic clusters are identified. Clusters are systems consisting of economic entities demonstrating development in a similar sector, formed by the location of related, complementary spheres of development in a certain geographical region, having a common infrastructure, technology, a single market, labour, opportunities for mutual establishment of trade relations, communication, mutual dialogue through the sharing of services. At the same time, it is assumed that competition and cooperation between small and medium-sized business entities in the clusters will be simultaneously ensured. Their demonstration of development within such a system gives a competitive advantage to small and medium-sized entrepreneurs. Consequently, with the introduction of the system, the costs of economic entities are reduced, marketing opportunities are expanded, productivity indicators are increased, their exports are increased, research and development opportunities are strengthened. At the same time, the promotion of new products, the creation of new industries, employment growth, leads to the development of regions, the improvement of infrastructure services. Clusters contribute to improving the material well-being of the population in the region by exporting goods and services in the form of groups of interrelated industries that serve to increase this location. Clusters cover the entire ring of the supply chain, support the provision of services, as well as dedicated infrastructure, which distinguishes it from traditional manufacturing industries.
Clusters have certain similarities, connections, and other trade among themselves, as companies and organizations with production ties demonstrate development in the same geographical area, they are formed.

Keywords: management of various types of risks, basic elements risk, innovation cluster, industrial cluster, competitiveness, economic efficiency

I. Introduction

With the cluster approach, it is important to take into account the self-development and self-organization of cluster structures. Clusters are not formed by chance; they are subjected to the requirements of the system. Clusters are subject to self-organization to a greater extent than other elements of economic entities. Synergy is a consequence of the joint use of specialized production facilities, scientific equipment, buildings, and engineering structures among groups of companies. It should be taken into account that in addition to the positive synergistic effect, a negative synergistic effect, which leads to an increase in risks for cluster participants may appear. Due to the synergistic effect, the authors of the article identified the risk of synergy (positive and negative synergy). To manage risks, an enterprise that is part of a cluster can be restructured to adapt to changes in the external and internal environment of the enterprise.

Restructuring of an enterprise, which does not affect the rights and obligations of a legal entity, is the creation of a new structural unit, the liquidation of a division, the merger of structural units, the creation of a subsidiary or affiliated company [2]. Reorganization of an enterprise that is part of a cluster, in the form of creating a cluster of an auxiliary legal entity together with other enterprises, in order to manage the risks of cluster operation.

Among the main goals of clustering, one can highlight: increasing the risk resistance of cluster participants through the introduction of new technologies. The formation and support of a cluster economic model is a promising way to increase the risk resistance of enterprises. In the process of interaction of enterprises with each other within the same cluster, it is necessary to reduce the production time of products in compliance with the necessary requirements for it from a technological point of view. The effectiveness of cooperation between enterprises can also be manifested in the distribution of risk and responsibility in the event of adopting an effective (losing) version of the development strategy. The lower the probability of new potential competitors entering the industry, the higher the synergistic effect from the interaction of enterprises with each other. The closer enterprises are dispersed within one cluster to the leading raw materials center, the lower the costs of transportation and storage of products, and the higher the possibility of finding additional reserves and attracting resources for the development of activities. The cluster approach assumes that the competitiveness and risk resistance of each individual enterprise is largely related to the competitiveness and risk resistance of other enterprises that are part of the same value chain or provide the external environment of the value creation process itself.

In a market economy, producers and consumers are always faced with possible dangers, risks and fear of losses. Risk in business is not only a possible threat, but also an absolute reality. Risks reduce tactical and strategic expectations regarding the future development of the enterprise and organization. At the same time, it creates a feeling of uncertainty and hopelessness in achieving set up goals.

In a market economy, most risk management must be carried out by entrepreneurs themselves. An entrepreneur must logically and thoughtfully accept the risk and evaluate its impact on business development. An entrepreneur always faces certain risks in the process of entrepreneurial activity. Those who want to earn a lot of money, of course, often have to take risks. This is the basic rule of business.

There are objective reasons for the occurrence of risks when doing business. Because it is impossible to calculate the influence of all factors on the activity of an enterprise in the first place. Therefore, some important points in the implementation of planned activities may change unexpectedly. That is why an entrepreneur can always face a loss during the operation of the company.

World economic science considers cluster associations as an effective tool for improving the performance and sustainability of individual enterprises. Formation clusters with the purpose of distribution of risks between participants in a cluster association seem to be an effective risk management tool. At the same time, the effectiveness of combining enterprises into a cluster is also associated with high uncertainty and risks. Incomplete grades, as how consequence, ineffective risk- management lead to the failure of cluster projects and large financial loss of participants. Thus, the development of theoretical approaches and methodological tools for effective risk management of enterprises in the context of cluster association is an urgent scientific task.[9]

One of the effective methods of risk prevention is diversification. The purpose of diversification is usually to improve the performance of enterprises and gain their positions in the market (Table 1).

Table 1: *Basic advantages use diversification onenterprise [9]*

Advantages	Characteristic benefits
1. Effective control of the risks	Losses in one area of activity are compensated by obtaining greater profits from the sale of other products, while at the same time losses in one area of diversification activity - the enterprise will no longer significantly influence its financial and economic condition. So how will its share in income spirit cease to be dominant?
2. More complete usage resources	Allows you to mitigate the seasonality of production, increase worker employment, receive additional income from the timely and thoughtful maneuverability of the industry, and increase volumes faster. The production of those types of products for which there is demand and form entails the required price.
3. Receipt enterprises synergistic effect	Defined as a type of cooperation, interconnected and cooperatively deployed actions that can manifest themselves in the form of strategic partnerships, mutually beneficial cooperation, mergers and cooperative interactions and those very same, in one and other conditions, that increase the efficiency of activities.

It seems that to identify and conduct a detailed study of the essence of risks affecting the functioning of cluster structures, it is advisable to distribute them into general risks of enterprises and specific cluster risks. Of course, the formation and functioning of clusters are associated with many common enterprise risks that are characteristic of any organizational and legal form of the companies. Analysis of the conditions of formation and the functioning of industrial clusters allows us to identify two traditional areas of risk occurrence: the external and internal environments of the cluster, which determine the stability and efficiency of the cluster formation. [9].

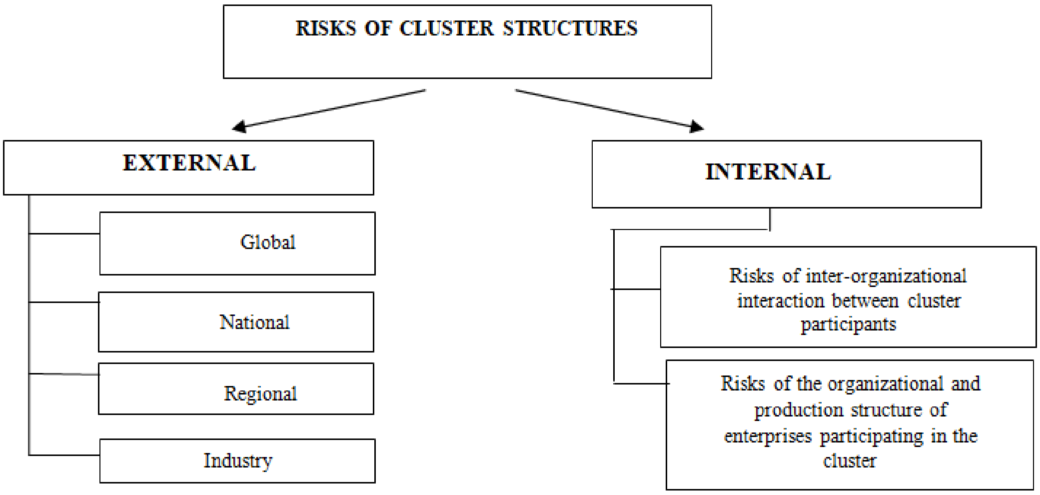

Figure 1: *General classification risks cluster structures.*

In modern economic science, innovative clusters are viewed as locomotives of economic progress due to their ability to enhance the competitiveness and innovation of businesses, and address issues related to employment, industry, and regional imbalances.

As regional entities, innovation clusters have an impact on the economy of the entire nation, given the intrinsic relationship between regional and national economic development. Innovation clusters that promote regional growth are integral to advancing the country's overall development. Furthermore, paradoxically, in the context of globalization, the significance of innovation clusters and their growth intensifies, as they have the potential to generate international and even global repercussions.

Globalization enables companies to allocate their resources and operations to the most suitable locations. Therefore, the wider the reach of globalization in markets, the greater the likelihood of resource flows being directed towards regions that offer the most favourable business environments, thereby enhancing the significance of clusters and regional specialization. Further specialization within clusters promotes relationships with other clusters that deal with complementary values, fostering economic cooperation among neighbouring states instead of territorial disputes, resulting in mutual benefits for each state's economic development and stability in regional and domestic politics.

The interpretation of the "cluster" concept is shaped by the scientific approaches adopted by researchers studying the economic clustering process from various academic disciplines. It is worth noting the distinctive theoretical perspectives of different scientific schools. For example, scholars of the "America" ("California") school emphasized the significance of geographic proximity and shared specialization among enterprises, highlighting the interplay between competitive and collaborative mechanisms.

Representatives of the "Scandinavia" school highlights the central role of knowledge and innovation-driven interactions among enterprises in the development of regional and industrial clusters.

Muro M., Katz B. (Harvard Business School) noted the Four "Critical" characteristics of the cluster: proximity of enterprises and organizations included in it; connectivity factor of clusters; active forms of interaction between firms; The existence of a critical mass of participants in the cluster can affect the activities of the companies. [6]

It should be noted that the differences in the approach to defining the concept of "cluster" and the mechanisms of its formation led to the differentiation of the concepts of "industry" and "innovation" cluster.

An "innovation cluster" refers to a network of interdependent enterprises and affiliated organizations that complement each other and contribute to the advancement of innovation potential among each element of the cluster and the region as a whole. Some scholars perceive regional clustering as a gradual shift from innovative industrialization. Universities, engineering centres, and technological or innovation hubs serve as the nuclei of innovation clusters established through competence management, which entails acquiring new knowledge and sustaining innovation growth. The geographical scope of the technological chain underpinning the cluster may span across borders. Government support is an essential prerequisite for nurturing such clusters.

The main formation process for "industrial clusters" is technological chain (production process management) optimization and process management. State bodies may act as part of the cluster, but are not a mandatory component of it. The core of such clusters are companies that determine their technological and production integrity. The systematization of all of the above based on the analysis and generalization of leading scientific schools allowed the authors to distinguish 6 leading signs of territorial clusters:

1. Geographical proximity;
2. Critical mass of cluster participants;
3. General specialization of enterprises;
4. Competition;
5. Collaboration through knowledge-based relationships;
6. Innovativeness of production.

The term refers to the physical proximity, shared specialization of economic entities, dynamic competition and collaboration among all stakeholders, promotion of knowledge-based relationships, and active integration of all types of innovation into economic endeavours. [2]

Economic entities and participants of clusters encompass a wide spectrum, ranging from large corporations to small and medium-sized enterprises, scientific research organizations, and municipal and state authorities advocating for the advancement of regions and territories.

The disparity in defining clusters in foreign and local literature is contingent on the specific regional traits that shape their development. Most of the clusters are the result of the natural development process of the world economy and the territorial structure of its regions.

1. The research conducted unmistakably indicates that the concept of "cluster" has fortified its standing in contemporary economic science, and the tendency of fostering related legislation is discernible. Nonetheless, since there is no definitive scientific and legal clarification of the essence and features of clusters, there is a lack of consensus regarding their normative regulation.

2. The allocation of considerable financial resources of different levels of budgets for the creation and development of clusters gives special urgency to this problem. Therefore, the need for greater clarity in the understanding of the recognized category is not only derived from theoretical interests, but also aims to prevent inefficient spending of budget funds;

3. The notion of "cluster" was scrutinized, and a categorization of clusters in the economy was provided.

4. The research indicates that the economic clustering facilitates the formation of a comprehensive outlook on regional development policy, enhances the productivity, efficacy, and competitiveness of enterprises, widens the scope of innovation development, and optimizes interaction among diverse economic actors in the region, including the state, large and small enterprises, academic and research associations, and the public. Additionally, it leads to an improvement in the population's quality of life.

5. Cluster initiatives of regional economic development were explained. In addition, classification of the cluster development of economically developed countries and regions and analysis of the cluster structure of their economies and the obtained results are provided.

6. Institutions and tools for supporting and developing cluster initiatives in developed countries are reviewed.

II. Methods

Future research directions include analysing and proposing strategies for forming organizational structures for cluster management and determining their legal forms to ensure clusters' effective functioning. This includes considering internal factors as well as external challenges posed by globalization.

Research indicates that the term "cluster" was coined only three decades ago, during the final years of the 20th century. Nevertheless, governments of developed nations view the creation of innovative clusters at a regional level as a key driver for economic growth and recovery, despite its relatively recent emergence as a concept.

As the concept of cluster has various interpretations, it is more significant to examine it as a factor of economic growth and competitiveness from a political-economic standpoint. Therefore, in this context, a cluster can be described as:

1. Clusters are defined by some authors (implicitly or explicitly) as geographically close groups of firms that mainly produce the same product or service;

2. Clusters are a group of interconnected industrial enterprises located in a close geographical area;

3. Clusters are networks of firms, especially small and medium-sized enterprises and related institutions, within geographical boundaries, and organizations that cooperate with other enterprises that use the same basic technology.

The global search for ways to enhance the competitiveness of national economies has shown that the creation and advancement of clusters are worthwhile. The acceleration of globalization necessitates effective solutions for the issue of economic clustering at both the national and regional levels.

Michael Porter, a professor at Harvard Business School, is a prominent figure in the field of competition and competitiveness research in the United States. He is the founder and advocate of the cluster theory in economics and the author of the theory of competitive advantage. Porter suggests that competitive firms in a particular industry can be found concentrated in a specific region or country. In his book "The Competitive Advantage of Nations" (1990), he proposed a theory of national, state, and local competitiveness within the global economy. This theory highlights the significance of clusters and underscores the importance of understanding the role of geographical location in shaping the competitive advantage of clusters, rather than individual firms and industries in isolation [1].

M. Porter has developed multiple definitions of the cluster phenomenon, and each of them is characterized by its own unique features and particularities. One of the most common definitions is as follows: "a cluster is a group of companies and related organizations operating in a certain area, characterized by joint activity and complementing each other, geographically close to each other." The scientist also defined the cluster as "a system of interconnected firms and organizations whose value as a whole exceeds the simple sum of its constituent parts", thus emphasizing its synergistic effect. In Porter's definitions, attention is paid to the main features such as geographical concentration (localization) of cluster members, close ties between cluster members, and the combination of competition and cooperation in the cluster.

M. Porter suggests that clusters are more effective than individual industries in achieving a balance between competition and competitive advantage. Clusters can leverage linkages, complementary industries, technology diffusion, expertise, information, marketing, and awareness of consumer needs. He further argues that the competitive advantages in the global economy are largely connected to the location of clusters, which benefit from the concentration of specialized skills and knowledge, institutions, interconnected economic activities, and consumers in a specific geographic area [3].

Clusters can be called local interconnected groups of small, medium and large enterprises and various research institutes that produce complementary products, compete and at the same time cooperate.

In this regard, M. Porter called for the funds earned in the commodity sector to be directed to the diversification of the economy and the development of clusters.

The classical clusters proposed by M. Porter in 1990 are distinct from the innovative clusters that are currently being studied and formed. While Porter's original approach to clusters was innovative, aiming to improve professionalism, specialization, customer relationships, and complementary products and services, the goal of innovative clusters is to establish more sustainable production and service facilities, associations, and start-ups by introducing new techniques and technologies. This includes constant development, enrichment of new ideas and analytical tools, and maintaining the dynamism of developing clusters.

The clustering of the economy of individual territories determines their most efficient integration into the world economic system, allows for the collection and optimal use of resources in terms of global trends, and helps to increase the efficiency of the state's industrial policy. Clusters have become one of the main driving forces and determinants of the competitiveness of geographical regions, their effectiveness is confirmed by world experience. Clusters allow to increase the competitiveness not only of their enterprises, but also of specific areas of activity within the region, including expanding the application of innovations, reducing transaction costs, developing and strengthening relations between business, science and the state.

Cluster policy is traditionally understood as a set of measures aimed at increasing the competitiveness of the national economy by stimulating the development of clusters.

Synergistic and synergistic benefits obtained from the organization of a cluster consist not only of increasing the efficiency of its work as a whole compared to the efficiency of individual participants, but also of mutual strengthening of the competitive positions of both industrial production and the territory it covers.

As previously noted, the use of regional economic clustering is increasingly being utilized to enhance the effectiveness of the entire economic system of countries worldwide. The growing number of cluster initiatives in numerous countries, including both developed and developing nations, have demonstrated their feasibility and efficacy. Cluster policy is now integrated into the innovative and regional development strategies of various countries globally, and clusters have become crucial to their economies.

The most important factor for increasing the efficiency of industrial production in cluster enterprises is the improvement of management within the framework of the creation of an information system for the management of industrial clusters.

The possibility of evaluating the efficiency of the presence of clusters through the assessment of its organizational cost and competitiveness can be considered. In this approach, the evaluation of competitiveness of clusters is carried out from three positions. The assessment of the dynamics of market positions is carried out through the analysis of the change in the share of cluster enterprises in the industrial volume of production in the world market; increase in export volumes for the cluster; the number of new markets in which firms - cluster participants participate.

Another methodology for evaluating the efficiency of the newly created cluster consists of 5 integral characteristics. Each of them consists of several assessment criteria that have different weights during the analysis:

1) Availability of competitive enterprises;
2) Implementation of innovative projects;
3) Increasing the economic indicators of the field;
4) Existence of mutual relations between cluster participants;
5) Geographic proximity of cluster participants, correct choice of cluster participants and their number.

The analysis examines various indicators to evaluate the success of cluster enterprises. These include the growth of economic indicators in the industry, the increase in the share of work and services provided by cluster enterprises, the percentage of employees working in cluster enterprises compared to the total number of employees in the industry, and the updating of main assets through increased investments in the region. The effectiveness of relationships between cluster participants is evaluated based on their ability to cooperate, create necessary infrastructure, and the managerial skills of the heads of the cluster enterprises. The selection of cluster participants, including their number and geographical proximity, is assessed by considering the territorial location of participants and the selection of the minimum number of enterprises with the maximum share of their participation in the internal market [7]

When evaluating the economic efficiency of industrial enterprises in the conditions of clustering, the following must be taken into account:

1. Cluster life cycle,
2. The interests of each economic entity included in the cluster,
3. Evaluation of efficiency at three levels: enterprise, region, territory.

III. Results

Six key characteristics can be identified for cluster derivatives of industrial enterprises formed in different regions of the world. Some of these characteristics describe the participants of the cluster, such as the leading enterprise that connects all the other participants in the value chain and smaller enterprises with a higher level of innovation in their production processes. Others determine the direction of development for the enterprises, such as a focus on internationalization through direct foreign investments and export of the final product. The formation of clusters cannot occur without direct or indirect support from the state. State cluster policies stimulate the development and improvement of relationships and competition in both domestic and foreign markets. In a free market environment, competition between companies plays a decisive role in the cluster. The more producers there are of the same product, the more efficiently the cluster market mechanism works, leading to lower production costs for the final product. [4]

Innovative cluster enterprises also have the following positive effects:

1. Effects of production scale (provides a multiplicative effect of cluster operation due to the interaction of companies);
2. Covering effect (occurs when the production factor is used in the production process of not one, but several types of products);

3. Synergy effect (an effect resulting from the movement of coordinated mechanisms in time and space, which is essentially different, but causes fundamental qualitative changes in the entire system under consideration);

The presence of these effects enables cluster enterprises that experience losses in the short term to overcome difficulties and achieve significant competitive advantages in the long term. The nature of innovation clusters gives them the ability to provide substantial benefits to their participants by combining cooperation and competition within the cluster, resulting in a synergistic effect that enhances the competitiveness of the entire system. In comparison to industrial clusters, innovative clusters are comprised of organizations that generate new knowledge, such as research centers or universities. This allows for the coordination of efforts and funding to create new products and technologies, as well as the formation of a complete technological chain, beginning with the conception of an idea and ending with the introduction of new products to the market.

The economic effect created by innovative clusters is the object of analysis of many scientific articles and studies, the results of which have been published in the last decade. In modern economic science, innovative clusters are considered locomotives of economic development.

Based on all this, in general, assistance (support) to the formation and development of innovative clusters by regional authorities should be implemented in the following directions:

• Creation of conditions for constructive dialogue between business and government, alignment of interests of cluster members and strengthening of cooperation between them;

• Stimulation of demand, formation of consumer preferences in the region, development of related and supporting areas of the economy, state orders;

• Development of the vocational education system in order to form the necessary competencies in the region;

• Development of foreign relations, elimination of trade barriers, protection of intellectual property rights, implementation of joint infrastructure and investment projects;

• Creation of favorable economic, institutional and other conditions in the region;

Innovation clusters, which operate at a regional level, have a significant impact on the national economy due to the direct link between regional and national development. Nevertheless, their importance extends beyond the national level as they can have international and even global impacts, especially in the context of globalization.

In addition to the above, in the organization and management of clusters, not only in the public sector, but also in the private sector, the attitude towards this field should be strengthened and a sufficiently efficient environment for entrepreneurs should be created.

One of the advantages of cluster management of an industrial enterprise is the ability to concentrate management influences on the most promising areas of activity and their support. The cluster is a sustainable territorial-industry partnership of enterprises and entities united by an innovative program for the introduction of advanced technologies to increase the sustainability of cluster participants in the market of manufactured goods, works, and services. The cluster includes independent enterprises, the cooperation of which is beneficial to each of the participants and generally increases their sustainability and profit.

IV. Discussion

The cluster development stages are as follows: at the formation stage, cluster members collaborate around the main activity and explore common opportunities, making it impossible to assess effectiveness. Thus, only economic activity indicators such as the dynamics of Foreign Direct Investments, production volumes, state support, and the number of jobs created can reflect the actual situation. Since performance indicators are not considered at this stage, the efficiency weight index value will be 0, while the performance will be 1.

During the "development" stage of the cluster, the area of interaction between the cluster members expands, new participants are involved in the work, and new formal and informal institutions are formed. At this stage, it is possible to evaluate the activity of enterprises in terms of both efficiency and productivity on all the proposed indicators.

The stage of "maturity" is determined by the degree of reaching a certain critical mass of participants, which allows forming and permanently maintaining constantly updated relations between cluster members. At this stage, it is possible to use all the recommended indicators (except for the number of jobs created).

In the "decline" stage, some indicators can no longer show positive dynamics (for example, the growth rate of the production volume, the company's market share, the number of highly productive workplaces, the volume of shipped innovative products and scientific-research works).

To put it differently, the approach suggested for evaluating economic efficiency allows for a range of values between 0 and 1 for the economic efficiency index.

$$0 < I_{EE} < 1$$

The lower the value of the index, the lower the economic efficiency of the enterprises in the cluster.

Our opinion is that contemporary approaches to assessing the effectiveness of clusters should consider the various stages and factors involved in their development, along with the concerns and objectives of all involved parties. It's important to note that the methodology we propose is only applicable for evaluating clusters that are of the same type and can be compared.

In clusters, higher labor productivity is achieved, as well as higher employment opportunities. At the same time, the role of regional authorities is as follows: using information opportunities to attract new participants to clusters; tax policy stimulating the development of clusters; simplification of establishment procedures; facilitating access to start-up and venture capital.

Constant improvement of worker qualifications is a crucial requirement for successful economic clustering in the rapidly evolving technological landscape. However, US companies are currently falling behind their counterparts in Europe and Asia in terms of investing in their employees' training, both in production and otherwise. Compared to regions like Europe, Japan, and Southeast and Southwest Asia, US employers allocate fewer resources per employee towards training.

The evaluation of the economic efficiency of the clusters consists of 6 main stages:

Stage I: The assessment of cluster formation involves examining various factors such as proximity of the businesses, common areas of specialization, number of participants, collaboration on scientific research and innovation, competition and cooperation. It's important to note that the absence of any of these factors would make it inappropriate to evaluate the performance of the cluster.

Stage II: The selection criteria can be evaluated by determining the nature of the clustering action factor, such as forming pairs of factors like foreign direct investment, executive directions, the primary consumer, and market competition and innovation for small and medium businesses.

In order to develop the cluster on the basis of "direct foreign investment-export directions", it is absolutely necessary to analyse the indicators of the volume of foreign direct investment and export.

If the cluster is formed and develops on the basis of the main consumer - market/competition, then the price indicator is the organization of the number of workplaces, the volume of production, tax and profit of the enterprise in the market. If the enterprise cluster works on the basis of "innovation - small and medium-sized business", then the issues of evaluating the volume of scientific research and construction works, the volume of innovative products and the organization of workplaces must be analysed.

Stage III: Efficiency and result indicators are employed to assess the performance of industrial companies within the cluster, and these are referred to as selection indicators.

The level of achieving the planned result characterizes the final result. For example: the organization of the number of jobs, innovation products, exports, taxes, etc.

Taxes allocated to the population, growth rate of production volume, export level; the rate of growth of the enterprise in the market and the volume of state aid characterize the efficiency indicators.

For an objective assessment of the result, the cumulative index of efficiency can be used. Which is calculated as the sum of the achieved indicators of the planned results:

$$I_{ef} = \sum_{n=1}^{k} \alpha_n R_{fh}/R_{ph}$$

Here, I_{ef} - integrated productivity index;
R_{fh} – the actual indicator of productivity;
R_{ph} - planned indicator of productivity;
K is the sum of indicators, $0 < \alpha_n > 1$, if the indicators are equal, then $a_n = 1/K$
We propose to calculate efficiency as a cumulative index. This is calculated as the sum of quality indicators of the achievement of results:

$$I_{ec} = \sum_{n=1}^{k} b_n E_{fn}/E_{pn}$$

Here I_{ec} is the integrated efficiency index,
E_{fn} – the actual indicator of efficiency
E_{pn} – planned indicator of efficiency,
K' is the sum of indicators, $0 < \beta_n > 1$, if the indicators are equal, then $\beta_n = 1/K'$
Thus, the economic efficiency can be calculated as the subtotal of the total efficiency index and the efficiency index:

$$I_{EE} = {}^1/_2\, I_{ec} + {}^1/_2\, I_{ef}$$

Here:
I_{EE} – economic efficiency,
I_{ec} – efficiency index,
I_{ef} – general index of results (integral index).

Stage IV: Selection of signs characterizing the efficiency of the work of different types of economic subjects. It is proposed to distinguish:

1. Large business enterprises (main manufacturers),
2. Enterprises belonging to medium and small businesses,
3. Research and educational institutions.

At this stage, it is necessary to evaluate the activity of each enterprise in terms of its characteristics and possible participation in the cluster work.

Finally, the calculation of efficiency or effectiveness indices is carried out on the basis of specific indicators. For example: the efficiency index for large business enterprises is calculated by the following formula (number of indicators K=3).

$$I_{efbb} = 1/3\Delta V_{prf}/\Delta V_{prp} + 1/3\Delta V_{exf}/\Delta V_{exp} + 1/3\Delta WP_f/\Delta WP_p$$

Here:
I_{bb} – efficiency index of large business enterprises,
ΔV_{prf} – dynamics of actual production volumes,
ΔV_{prp} – dynamics of planned production volumes,
ΔV_{exf} – dynamics of actual export volumes,
ΔV_{exp} – dynamics of planned export volumes,
ΔWP_f – the dynamics of the number of actual workplaces,
ΔWP_p – the dynamics of the number of planned workplaces.

Stage V: Determining the efficiency of cluster work and its criteria, taking into account the development interests of enterprises, the region as a whole or a separate field.

To assess the development of individual businesses, it is crucial to analyze changes in production volumes, adoption of innovative products, market share, and employment rates. Indicators of sustainable growth in both domestic and foreign markets can be determined by evaluating export volumes and the share of industry enterprises in the market. The indicators of socio-economic progress in the regions include the number of new jobs (including high-productivity roles) and the trend of taxes per capita. The selection of indicators at this stage is based on a similar approach to the previous stage.

Stage VI: Consideration of the possibility of realistic evaluation of activity indicators at different stages of the development of cluster enterprises. For the correct assessment of economic efficiency, it is necessary to take into account the weight of each of the indices:

$$I_{EE} = j_{ec}I_{ec} + j_{ef}I_{ef}$$

Here:
I_{EE} – Economic efficiency,
I_{ec} – Efficiency index,
I_{ef} – Consequentiality index,
j_{ec} – Efficiency weighting factor,
j_{ef} – is the activity measurement factor.

The significance of the weighting coefficients varies in all four stages of production and is directly proportional to the number of indicators considered in calculating the integral productivity indices.

The weighting coefficients are assigned greater importance as more indicators are included in calculating the integral productivity indices, and this varies across the four production stages. The efficiency weighting factor is determined by dividing the efficiency or effectiveness indicators considered during the analysis by the total number of such indicators evaluated for that particular stage of cluster development.

$$j_{ec} = N_{ec}/(N_{ec} + N_{ef}); \quad j_{ef} = N_{ef}/(N_{ec} + N_{ef})$$

Here,
j_{ec} – the efficiency weighting factor,
j_{ef} – activity measurement factor,
N_{ec} – the number of analyzed indicators of economic activity and
N_{ef} – the number of analyzed indicators of economic activity.

Abstract

The article considers the problem of taking into account the impact of climate change on the functional reliability (FR) of regional road networks. An algorithm and methodology for assessing the FR of a road are proposed, which are based on assessing the durability and residual life of the road surface structure according to deformation criteria: (1) the maximum permissible residual deflection of the road surface, (2) the maximum permissible reduction of the road surface material elasticity modulus as a result of multiple elastic-plastic deformation of the road surface under the action of traffic, (3) the appearance of unacceptable longitudinal track(s) and/or potholes in the road surface.

Keywords: functional reliability, transport network, climate change, durability, residual resource

I. Introduction

The problem of assessing the reliability of a developed road network is very relevant, especially in light of the increasing complexity of transport and logistics chains, the constant growth of transport traffic, the degradation of the road surface from the impact of transport, temperature changes, adverse weather conditions, climate change, frost upheaval, earthquakes, mudflows, landslides, avalanches, destruction and demolition of bridges due to floods, insufficient funds for repairs, etc. The criterion for the road network failure is road surface deformation.

The functional reliability (FR) of a regional road network is understood as the reliability of the main route for which this network is intended. The main route FR is equal to the product of the reliabilities of the network sections that form it.

In the case where the main route consists of several equivalent routes, its reliability is calculated using the formula:

$$R_n = 1 - Q_1 \cdot Q_2 \cdot \ldots \cdot Q_n, \tag{1}$$

Where $Q_1 \cdot Q_2 \cdot \ldots \cdot Q_n$ are the probabilities of failure (POF) of paths n in number that make up the main route.

Calculation of network reliability shows that the more equivalent paths the selected route is organized by, the higher its reliability and, accordingly, the higher is the entire transport network the reliability.

II. Mathematical model of the road network

When assessing the functionality of a transport network, its mathematical model is used, with the help of which each driver of a vehicle selects a route, calculates the travel time and the traffic flow on each road. The stationary distribution of traffic is found as the solution of the optimization problem of the transportation network functioning [7]:

$$min\ Z(x) = \sum_i \int_0^{x_i} t_i(w)dw\ , \qquad (2)$$

Where x_i is the volume of traffic on the road i; t_i is the travel time on the road i:

$$t_i(x_i) = t_0(1+\alpha\left[\frac{x_i}{C_0 \cdot N_L}\right]^\beta), \qquad (3)$$

where t_0 is the time of unimpeded passage on the *i-th* road; C_0 is the capacity of one traffic lane; N_L is the number of lanes of the *i-th* road; α and β is the variable parameters defined as 3.0 and 4.0 respectively for design speeds of 20 km/h and 30 km/h and 4.5 for design speeds of 40 km/h and above [7].

The total travel time of the road is determined as follows:

$$C_i = \sum_i t_i(x_i)\delta_i\ , \qquad (4)$$

Where δ_i is a logical function that indicates whether the selected route passes along the *i-th* road.

III. Simulation of real-time traffic flow after an accident using an agent-based model

Agent-based modeling is a powerful method for analyzing distributed complex systems, suitable for modeling systems under three conditions: the problem domain is spatially distributed; subsystems exist in a dynamic environment; subsystems must interact with each other with greater flexibility [7].

IV. Initialization of the agent-based model [7]

With continuous monitoring of road traffic (including with the help of video cameras and drones), information is accumulated about the travel time of each vehicle and the volume of traffic flow on each road of the transport network. In this case, the number of cars on each road I_i, is:

$$I_i = x_i \cdot t_i \qquad (5)$$

The probability that a particular car on the *i-th* road will take a particular route k between an origin r and a destination s is [7]:

$$\Pi_{i,rs} = \frac{\sum_{k\in\Psi_{rs}} f_k^{rs}\delta_i}{x_i}, \qquad (6)$$

where f_k^{rs} is the traffic volume of the *k-th* route between the source point r and the destination point s; Ψ_{rs} is the set of all routes between r and s.

Using equation (6), each car on the *i-th* road is randomly assigned a direction of travel. The probability that an individual car assigned a particular direction of travel *r-s* will travel a particular route *r-t* is [7]:

$$\Pi^{rs}_{i,rt} = \frac{f^{rs}_{rt}\,\delta_{i,rt}}{\sum_{k\in\Psi_{rs}} f^{rs}_{k}\,\delta_{i}} \quad (7)$$

Using equation (7), each vehicle on the *i-th* road is randomly assigned a route. Assuming that the vehicles are uniformly distributed across the roads (links in the transport network), the time it takes for the *j-th* vehicle in the queue to reach the intersection between the links is [7]:

$$t_{j,a} = t_i(x_i)\cdot\frac{j}{I_i} \quad (8)$$

V. Algorithm for assessing the durability of road surfaces

The durability of a road surface is usually understood as the time during which it retains its basic properties at a level that satisfies operational requirements.

Currently, to assess the durability of the road surface of a specific section of the road network, the initial reliability is set (the probability of failure-free operation at standard average values of the strength and rigidity parameters of the road surface).

From the standpoint of reliability theory, a highway is a recoverable system. Since analytical calculation of recoverable network systems reliability as yet has not been developed, the highway during the time between repairs is considered as a non-recoverable system [4].

Elements of non-repairable systems have the following durability indicators [4]:

$P(t)$ is the probability of failure-free operation of an element during time t (lifetime function);

$f(t)$ is the density of distribution of time between failures;

$\lambda(t)$ is the failure rate at time t;

T_0 mean time between failures;

P_0 is the initial reliability of an element (the probability of failure-free operation at standard average values of the strength and rigidity parameters of a road).

The following relationships exist between durability indicators [4]:

$$P(t) = P_0 e^{-\int_0^1 \lambda(t)dt} \quad (9)$$

$$T_0 = \int_0^{\infty} P(t)dt \quad (10)$$

These expressions show that the initial function in the durability calculation is the failure rate. To determine the durability (mean time between failures) of a road surface, the Weibull distribution law is used:

$$\lambda(t) = \alpha\lambda t^{(\alpha-1)} \rightarrow P(t) = P_0 e^{-\lambda t^{\alpha}} \rightarrow T_0 = P_0\int_0^{\infty} e^{-\lambda t^{\alpha}}dt \quad (11)$$

The existing method of determining durability is not objective, since the initial reliability of the road surface is specified from regulatory documents during the calculation. For an objective assessment of durability, it is necessary to calculate the probability of failure-free operation of the road surface on each section of the road network.

The elastic moduli E_{total} and E_{min} are taken as random variables for assessing the durability of the road surface [5].

The reliability of asphalt concrete road surfaces as flexible road surfaces is determined by the permissible elastic deflection:

$$E_t \geq E_{min}\cdot K_{cr} \quad (12)$$

where E_t is the total calculated modulus of elasticity of the road surface structure, MPa,

E_{min} is the minimum required overall modulus of elasticity of the road surface, MPa,

K_{cr} is the required coefficient of road surface strength according to the elastic deflection criterion K_{cr} = 1,17 [2].

The value of the minimum required overall modulus of elasticity of the road surface structure is calculated using the empirical formula [5]:

$$E_{min} = 98,65 \cdot [\, lg(\sum N_p) - c], \ \ Mpa, \tag{13}$$

Where $\sum N_p$ is the total estimated number of load applications over the service life of the road surface;

c - empirical parameter adopted for different axle loads of a vehicle. For the maximum calculated axle load of 100 kN (with a lightweight type of road surface) c = 3.55.

To determine the durability for each section of the road network, it is necessary to determine the value of the minimum required overall modulus of elasticity of the structure E_{min}. To do this, it is necessary to calculate the total estimated number of load applications over the service life of the road surface on each section of the network according to [3], in the following sequence:

First, the prospective traffic intensity at the end of the inter-repair period N_{ps} is determined using the formula [3]:

$$N_{ps} = \ N_{in}(1+\frac{p}{100})^t, \tag{14}$$

Where N_{in} is the initial traffic intensity, vehicles/day;

p is the annual increase in traffic intensity, %;

t is the prospective period, years.

Then the traffic intensity N_p [3] reduced to the calculated two-axle vehicle is determined:

$$N_p = f_{st} \sum_{m=1}^{n} N_m \cdot S_{mt}, \ cargo\ units/day, \tag{15}$$

where f_{st} is a coefficient that takes into account the number of traffic lanes and the distribution of traffic across them;

n is the total number of different brands of vehicles in the traffic flow;

N_m is the traffic intensity of vehicles of the m-th brand (number of trips per day in both directions of vehicles of the *m-th* brand);

S_{mt}, is the total coefficient of reduction of the impact of the *m-th* brand vehicle on the road surface [3].

The multi-lane coefficient f_{st} is assigned according to Table 3.2 [3]. The roadway lane number is counted from the right in each direction of vehicle traffic. For two-lane roads f_{st} = 0.55.

Next, the total calculated number of applications of the calculated load to a point on the road surface during the service life is found using the formula [3]:

$$\sum N_p = 0,7 \cdot N_p \frac{K_c}{q^{(T_{lt}-1)}} \cdot T_d \cdot K_n \ , \tag{16}$$

Where q is the indicator of change in traffic intensity over the years;

T_{lt} is the estimated service life;

K_c is the summation coefficient;

T_d is the estimated number of days per year corresponding to a certain state of deformability of the road surface;

K_n is a coefficient that takes into account the probability of deviation of the total movement from the expected average.

The estimated service life T_{lt} is set according to table P6.2 [3].

The summation coefficient K_c is determined by the formula [3]:

$$K_c = \frac{q^{T_{lt}}-1}{q-1} \qquad (17)$$

For Eastern and Western Siberia, the calculated number of days per year corresponding to a certain state of deformability of the road surface is taken as T_d = 130 days [3].

The coefficient K_n, which takes into account the probability of deviation of the total movement from the expected average, is found from Table 3.3 [3].

Having data on the minimum and total calculated modulus of elasticity of the road surface of each section of the road, it is possible to determine [4,5]:

The average value of the bearing capacity reserve:

$$[g] = [E_t] - [E_{min}] , \qquad (18)$$

where $[E_t]$ – average value of the total calculated modulus of elasticity of the road surface structure;

$[E_{min}]$ - average value of the minimum required overall modulus of elasticity of the road surface structure.

The dispersion of the reserve of bearing capacity:

$$S_g^2 = S_{E_t}^2 + S_{E_{min}}^2 , \qquad (19)$$

Where $S_{E_t}^2$ is the dispersion of the total calculated modulus of elasticity of the road surface structure;

$S_{E_{min}}^2$ is the dispersion of the minimum required overall modulus of elasticity of the road surface structure.

Standard deviation of the bearing capacity reserve:

$$S_g = \sqrt{S_g^2} \qquad (20)$$

Where S_g^2 is the dispersion of the reserve capacity.

Reliability index:

$$\beta = \frac{\bar{g}}{S_g}, \qquad (21)$$

Where $\bar{g}$ is the average value of the bearing capacity reserve;

S_g is the standard deviation of the bearing capacity reserve.

And finally, the probability of failure-free operation, i.e. the reliability indicator of the road surface structure:

$$P(\bar{g} \geq 0) = 0{,}5 + F(\beta), \qquad (22)$$

Where $F(\beta)$ is the value of the Laplace function.

To determine the average values of elastic moduli, the variation coefficients are used:

$$[E_t] = \frac{E_t}{(1\text{-}C_{E_t})};\ [E_{min}] = \frac{E_{min}}{(1\text{+}C_{E_{min}})} \tag{23}$$

Where C_{E_t} is the coefficient of variation of the total calculated modulus of elasticity of the road surface structure, $C_{E_t} \le 0{,}2$;

$C_{E_{min}}$ is the coefficient of variation of the minimum required modulus of elasticity of the road surface structure, $C_{E_{min}} \le 0{,}2$.

The dispersions of elastic moduli are also determined using the coefficients of variation [5]:

$$S_{E_t}^2 = (C_{E_t} \cdot [E_t])^2;\ S_{E_{min}}^2 = (C_{E_{min}} \cdot [E_{min}])^2 \tag{24}$$

VI. Example of application of the methodology to the Ural Federal District road networks

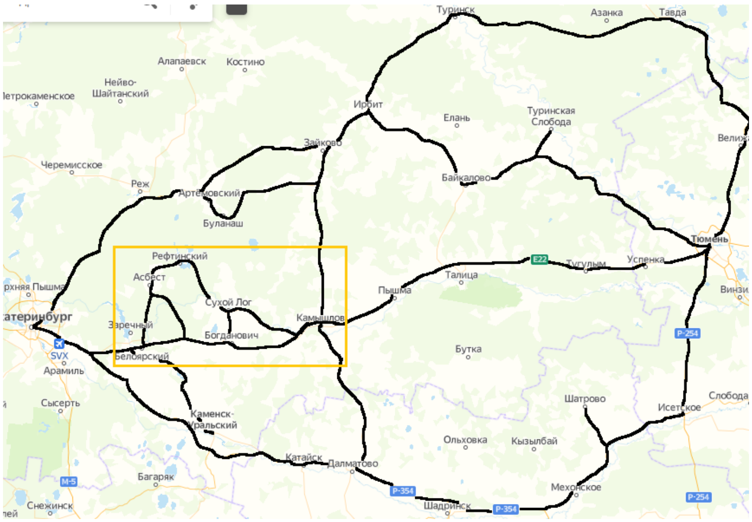

Figure 1: *The main road network with a highlighted area of the secondary road network in the Urals Federal District*

To assess the road surface reliability and durability, a network of highways (Figure 1) was selected, located in the Sverdlovsk, Tyumen and Kurgan regions of the Ural Federal District, which provides ground communication to two regional capitals: Yekaterinburg (with a population of over 1,5 million) and Tyumen.

According to the road-climatic zoning, the entire selected automobile network is located in the second road-climatic zone, II subzone, and is divided into following sections:

1) The main highway R-351 in the direction of Yekaterinburg-Tyumen through the intermediate settlements: Beloyarsky - Bogdanovich - Kamyshlov - Pyshma - Talitsa - Tugulym - Uspenka (length 330 km). Traffic intensity - 7980 vehicles/day.

2) Northern secondary direction Yekaterinburg-Tyumen through intermediate settlements: Artemovsky - Zaikovo - Irbit - Turinsk - Tavda - Velizhany (length 500 km). Traffic intensity - 5100 vehicles/day.

3) The southern secondary direction Yekaterinburg-Tyumen through the intermediate settlements: Kamensk-Uralsky - Kataysk - Dalmatovo - Mekhonskoye - Isetskoye (length 432 km). Traffic intensity - 6520 vehicles/day.

4) Direction Reftinsky – Asbest – Beloyarsky (length 57 km). Traffic intensity - 450

vehicles/day.

5) Direction Reftinsky – Sukhoi Log – Bogdanovich (length 61 km). Traffic intensity – 690 vehicles/day.

6) Direction Zaikovo - Kamyshlov (length 81 km). Traffic intensity - 750 vehicles/day.

7) Direction Irbit – Baikalovo – Talitsa (length 110 km). Traffic intensity – 800 vehicles/day.

8) Direction Turinskaya Sloboda – Tyumen (length 110 km). Traffic intensity – 2100 vehicles/day.

9) Direction Baikalovo – Turinskaya Sloboda (length 49 km). Traffic intensity - 1000 vehicles/day.

10) Direction Artemovsky - Bulanash - Zaikovo-Kamyshlov highway (length 73 km). Traffic intensity - 400 vehicles/day.

11) Direction Beloyarsky – Kamensk-Uralsky (length 72 km). Traffic intensity - 600 vehicles/day.

12) Direction Kamyshlov – Dalmatovo (length 80 km). Traffic intensity – 550 vehicles/day.

13) Direction Shatrovo – southern highway Yekaterinburg – Tyumen (length 22 km). Traffic intensity – 300 vehicles/day.

Using the above methodology, all necessary parameters of road surface wear for each section of the road network were calculated, the results of which are shown in [13].

Based on the obtained results, the initial reliability P (the probability of failure-free operation of the road surface structure at the beginning of road operation after the next repair) of each section of the road network was calculated, which is necessary for calculating the durability of the road surface.

A 100x50 km rectangle is selected from the main road network, in which all secondary roads adjacent to the main network are displayed (Fig. 1). The secondary road network has 30 nodes and 37 links.

To assess the maximum possible impact of a traffic accident on the capacity of the main route of the road network under study, a traffic accident was simulated. The accident was set at 9:00 (when the entire transport network is maximally loaded with vehicles) on the main highway R-351 in the direction of Yekaterinburg-Tyumen in the settlement of Gryaznovskoye, involving a fuel tanker, which led to a fire and explosion, with the subsequent destruction of a bridge structure. This made it impossible for vehicles to continue moving along this road until the bridge was completely restored [13].

The use of an agent-based model to analyze the consequences of the accident showed that the road accident led to a significant decrease in the speed of movement of vehicles and their accumulation, which directly depends on the speed of movement of cars. The average speed of the flow during normal functioning of the transport network is 57.5 km/h [11].

The destruction of the bridge as a result of the accident and the impossibility of driving along this section of the road led to the extension of the route along the main highway R-351 by 85 km (taking into account detours). The maximum time to bypass the destroyed section of the road using detours is $t_1=S/V=85/30=2{,}8$ hours, where S is the length of the detour, km; V is the average speed of movement along the detour, km / h.

The length of the bypass section of the road is 39 km. Provided that this section of the road is fully operational, the travel time along it t_2 at an average speed of 57.5 km/h is 0.7 hours. Time loss when bypassing the destroyed section of the road $\Delta t = t_1 - t_2 = 2{,}8 - 0{,}7 = 2{,}1$ hours. Thus, the travel time along the R-351 highway in the direction of Yekaterinburg-Tyumen in the event of the destruction of the bridge in the Gryaznovskoye settlement increases by 2.1 hours.

For a more accurate calculation of the probability of road pavement failure and the time tothe next repair, it is necessary to take into account all factors affecting the wear of the road pavement. In this regard, it is necessary to analyze the impact of each event on the probability of failure (POF) of the road pavement structure. One promising method for assessing and predicting the failure of any system with a large number of cause--effect relationships between events is Bayesian networks. BNs are graphical models that describe probabilistic relationships between a set of variables. Formally, they are directed acyclic graphs (DAGs), the nodes of which represent variables related to the system, and the arcs of directed action represent probabilistic dependencies between the variables [12]. Modeling a system with cause--effect relationships allows for a deeper understanding of the main mechanisms of its degradation and allowing studying how external interventions affect the system. The GeNIeModeler software package (hereinafter referred to as GeNIe) is used for this purpose. In this work, impacts, external influences, mechanical damage and the human factor are taken as factors influencing the probability of road surface failure.

When constructing a Bayesian network model to determine the probability of road surface structure failure, it is necessary to understand the circumstances leading to the object's failure. Due to the poorly developed system of monitoring road networks, the necessary statistics on road surface destruction are absent, therefore the conditional probabilities of failure of the road surface structure are specified by experts.

The probabilities of failure of the road surface structure on each section of the road network before the next major repair using the "GeNIe" software package are presented in [13].

According to the obtained results, the highest POF of the road surface structure is found in section № 9 (Q = 0.3176) in the direction of Baikalovo - Turinskaya Sloboda of the road network.

Communication between Yekaterinburg and Tyumen is provided by six routes with corresponding failure probabilities Q:

1) The main highway R-351 (Q = 0.2818);
2) The northern direction Yekaterinburg-Tyumen (Q = 0.2875);
3) The southern direction Yekaterinburg-Tyumen (Q = 0.2943);
4) The northern direction through the settlements of Baikalovo and Turinskaya Sloboda (Q = 0.4813);
5) The northern direction through the settlements of Zaykovo and Kamyshlov with an exit to the main highway R-351 (Q = 0.6397);
6) The main highway R-351 through the settlements of Kamyshlov and Dalmatovo with an exit to the southern road (Q = 0.613).

The reliability of the transport network under consideration in this case is equal to:

$$R_n = 1- 0,2818 \cdot 0,2875 \cdot 0,2943 \cdot 0,4813 \cdot 0,6397 \cdot 0,613 = 0,9955 \quad (25)$$

It should be noted that not all six routes could ensure the smooth movement of heavy-duty vehicles with a carrying capacity of over 20 tons. This is due to the fact that some routes have insufficient roadway width and weak points (bridges with reduced carrying capacity), which don't allow passing heavy-duty vehicles. For these reasons, routes No. 4 and 6 cannot ensure the movement of vehicles with a carrying capacity of over 20 tons. Hence, the reliability of the transport network along the Yekaterinburg-Tyumen route in this case will be determined only by: Main highway R-351 (Q = 0.2818); **N**orthern direction Yekaterinburg-Tyumen (Q = 0.2875); **S**outhern direction Yekaterinburg-Tyumen (Q = 0.2943); Northern direction through the settlements of Zaikovo and Kamyshlov with an exit to the main highway R-351 (Q = 0.6397).

So,the reliability of the network with respect to heavy-duty vehicles is:

$$R_n = 1- 0,2818 \cdot 0,2875 \cdot 0,2943 \cdot 0,6397 = 0,9847 \quad (26)$$

Calculation of network reliability shows that the more paths the selected route has, the higher its reliability, and, accordingly, the higher is the reliability of the entire transportation network. The results of calculating the residual resource (in years) of each section of the road network under consideration based on the elastic modulus of the road surface structure reduction criterion (formation of potholes on the roadway) are presented in [13]. The maximum permissible (critical) dimensions of a pothole are: length - 60 cm, width - 15 cm, depth - 5 cm.

One of the types of failure of the road surface structure is the formation of a rut on the roadway, as a consequence of decrease in the elastic modulus of the road surface structure during operation. The work [13] presents a calculation of the residual life of each section of the transport network based on the criterion of the formation of a longitudinal rut, the depth of which exceeds the maximum permissible value of 35 mm.

VII. Conclusion

The paper proposes a method for calculating durability and residual lifetime based on: the criteria of pothole and longitudinal rut formation, and the regional road network reliability based on the permissible residual deflection caused by multiple elastic-plastic deformation of the road surface under the influence of traffic.es

To determine the POF of each section of the road network, a method for assessing the initial reliability has been developed taking into account traffic and atmospheric) impacts and the human factor (violation of the asphalt concrete laying method), using Bayesian networks in the format of the GeNie software package.

The application of the developed methodology to the assessment of the FR of the Yekaterinburg-Tyumen route, showed that its reliability for conventional transport is 0.9955, and for vehicles with a carrying capacity of over 20 tons is 0.9847.

The use of an agent-based model of driver behavior for assessing and analyzing the vulnerability of the Yekaterinburg-Tyumen UFD transport network in the event of a main road failure due to a bridge collapse showed that the more developed the transport network is, the more robust it is.

The most vulnerable sections of the Yekaterinburg-Tyumen transport network in terms of road surface wear are**:** section No. 9 of the Baikalovo-Turinskaya Sloboda direction (with POF= 0.6824 and minimum failure-free service life of 4.5 years according to the pothole formation criterion), and section No. 10 of the Artemovsky-Bulanash direction (failure-free service life 4.39 years, with POF= 0.6842).

Abstract

In recent years, important steps have been taken in the direction of expanding the use of electric cars in our country. Electric cars are considered environmentally friendly as they do not run on fuel. Electric cars are quiet and comfortable. There are three types of electric cars. Fully electric, hybrid and plug-in. Fully electric forms of hybrid electric cars are designed for short distances. Because their energy decreases on a long journey and it is necessary to re-accumulate energy. Some cars use solar energy to provide part of their electricity needs. Solar panels are used to power electric motors and charge batteries. They only get energy from the sun during the day. In this paper, another construction for long-distance electric vehicles is proposed. By installing piezoelectric materials in the wheels of electric cars, their long-distance movement is ensured. Unlike electric cars, where solar panels are installed, piezoelectric materials will provide additional electricity at any time when the cars are moving, not just during the day. In electric cars, since piezoelectric materials are installed on the tires, they will not need additional structural changes.

Keywords: electric car, solar panel, piezoelectric material, electric batteries, electric vehicles, wheels

I. Introduction

Electric cars are safer not only for nature, but also for passengers. Their maneuverability is higher than that of cars powered by conventional energy sources. Currently, climate change is one of the global problems that concern the world. Azerbaijan has not been left out of the influence of global climate changes. In the last 100 years, average annual temperatures in the territory of Azerbaijan have increased by 0.4-1.3^{0}C. Against the background of climate changes, Azerbaijan is experiencing floods, avalanches, storms, hurricanes, surges, strong winds, heat, droughts, melting of glaciers, salinization, land degradation, desertification, reduction of precipitation and water resources, etc. exposed to the effects of such extreme climate events. One of the main factors in environmental pollution is the transport sector [1]. The increase in vehicles is rapidly increasing the risks to the environment. One way to reduce these risks is to increase the share of electric vehicles in the transport sector. There are difficulties in the matter of power supply of electric vehicles. Works aimed at eliminating these problems will directly create conditions for reducing environmental risks. The 29th session of the Conference of the Parties to the UN Framework Convention on Climate Change - COP29, which is hosted by a different country every year, in Baku this year also means global support for Azerbaijan's green energy policy. At present, light material is mainly used in the production of electric vehicles. Thanks to the use of environmentally friendly fuels such as electricity, most urban vehicles (taxis, company and service vehicles, etc.) have no exhaust gases, which makes them promising for use in urban environments.

Currently, many well-known car manufacturing companies have started producing their own electric cars. The power of German-made electric cars has been increased to 544 horsepower. US-made electric cars have four electric motors. There are 105, 135 and 180 kWh batteries. It has a range of 370 to 660 km. These cars can accelerate from 0 to 100 km/h in about 4.4 seconds, just like internal combustion engine cars.

"National Program on Electromobility" is being prepared in our country. There is an order of the Minister of Energy of the Republic of Azerbaijan on the creation of a working group on "Preparation of the National Program on Electromobility". The working group will prepare and implement measures for the development of electromobility.

In recent years, important steps have been taken in the direction of expanding the use of electric cars in our country. From 2022, the import and sale of electric cars and level 2 and 3 electric chargers for them are exempted from VAT. More than 100 electric car charging stations have been installed in the last year. Since last year, the application of the customs duty on the import of electric motor vehicles that have passed the factory release date up to 3 years has been suspended. Statistics show that after these measures, the import of electric cars to the country has increased significantly. So, last year, 3,102 vehicles powered by an electric motor were imported to Azerbaijan worth 125 million 268 thousand US dollars, which is 7.1 times and 6.4 times compared to 2022, respectively, compared to 2021 in comparison, it is 36.2 times and 19.4 times more.

However, in order to promote the use of electric cars, it is not only the reduction of import and sales prices, but also the creation of favorable infrastructure that is important. In other words, electric cars should have a sufficient number of charging points, spare parts warehouses, and quality service should be provided to them. A lot of work has been done in Azerbaijan in the direction of creating such infrastructure.

Usually, some companies that sell electric cars say that the car can travel about 400 kilometers after charging. Experience shows that this car cannot travel even 250 kilometers with an electric engine. Solving these issues requires special attention and control in the area in question.

Electric cars are considered environmentally friendly as they do not run on fuel. Electric cars are quiet and comfortable. There are three types of electric cars. All-electric forms of electric cars in all-electric, hybrid and plug-in hybrid forms are designed for short distances. Because their energy decreases on a long journey and it is necessary to re-accumulate energy. Hybrid cars work with both gasoline and electric engines. Such cars use the electric motor when driving and driving at low speeds, and as the speed increases, the gasoline engine starts to work. The battery of a hybrid car is technically designed for long journeys, as it can collect energy by itself while driving, while the gasoline engine is running, and when it is stopped. Plug-in Hybrid cars, unlike normal hybrids, have batteries with external electrical storage capacity. Such cars can be used on long roads thanks to their powerful batteries.

Taking into account the demand for electric cars, projects related to the production and export of this type of cars are expected in Azerbaijan in the coming years. In total, 8,000 cars are planned to be produced in Azerbaijan in 2024, of which 6,000 are passenger cars, and 2,000 are trucks and buses. The price of cars starts from 17,800 manats and this figure varies up to 160,000 manats.

Due to the lgots for the use of electric cars, their importation to our country, low operating costs, and their environmental friendliness, they replace those working with traditional energy sources more and more every year.

Over the years, energy prices are rising, and it is becoming more difficult to obtain it. Clean energy is being used all over the world. The electric car market is one of the best solutions to these problems. This market has great potential for long-term growth: as expected, the vast majority of cars in the world will be electrified in the near future.

Silent operation, comfort, modern design, simple management and maneuverability of electric cars allow for their wider application.

The developers of their electric cars are working to cover longer distances with a smaller battery. In this regard, everything is simpler with regular buses - the route is known, the distance is also known. Taking all this into account, the American AEM presented to the public the latest version of the 18-seater electric bus E-Shuttle.

II. Methods

The transition to electric vehicles has not always been straightforward. One day, John Mountey, a resident of the United States, decided to completely stop burning fuel. He took the 1994 "Geo Prism" sedan, the Toyota Corolla car produced jointly with "General Motors" under his own brand, and threw the internal combustion engine into the landfill. Many components were sent for recycling: engine cooling system, exhaust pipes, catalytic converter, fuel tank, clutch basket, etc. There was a lot of free space under the hood. But it didn't take long for the new electric motor to occupy a significant part of the space. It is mated to a standard manual transmission locked in second gear. The entire bottom is covered with a large battery. More precisely, there are 50 of them: two sections of 25 12-volt lead-acid batteries.

Additional details: power steering, brake master cylinder and air conditioning system are connected to the electric motor. These are the standard items available. But the water tank with a small heater is new. Of course, heating does not always mean "free" in cars with an internal combustion engine. The gearbox has been changed to make it easier to switch between forward and reverse. A socket is installed instead of the fuel tank mouth. Charging can be done from 120 or 240 V networks. And of course the fuel sensor has been changed to a voltmeter. John Mountey left all other systems unchanged.

Let's say that the standard Geo Prism sedan consumes no more than 10 liters of fuel per 100 km. It turns out that the internal combustion engine will burn 8 liters in 80 km. While the average price of gasoline is 1 AZN/liter, it turns out that a trip of 80 km costs 8 AZN. According to John Mountey, only 12 kW of power is needed to fully charge the batteries of his electric car. The tariff in Baku is AZN 0.08 per 1 kW. If you charge the car during the day, this procedure costs AZN 0.96! In the latter case, each kilometer traveled by car is 8 times cheaper than a standard car. Such savings can only be dreamed of. The disadvantage of operating electric cars is quite obvious: the need for constant recharging. And the maximum mileage is not important here: whether you travel 50 km or 300 km from your home, it is very difficult to find a free outlet. Moreover, the charging procedure requires an average of about 8 hours! You can completely forget about traveling on such transport. It turns out that the destiny of electric vehicles is purely urban use. Here we can add that hydrogen fuel cars are exactly the same as electric cars. The only difference is in the way the electric motor is powered. In the first case, this is the charge of the batteries, and in the second, the energy of the chemical reaction of hydrogen decomposition. But filling a full tank of liquid hydrogen takes no longer than a regular tank of gasoline. The only question is infrastructure.

Solar electric buses (solar cars) are a type of electric buses that move using solar energy. It uses solar panels to power electric motors and recharge batteries. Like an ordinary electric bus, the sunmobile moves at night, and during the day it has enough energy from the sun [2].

The drawback of electric cars is quite simple: the need for constant charging. And here the maximum mileage is not important: it is very difficult to find an electric charger, whether you travel 50 km or 300 km from your home. Moreover, the charging procedure takes about 8 hours on average (15 minutes at special stations)! You can completely forget about traveling in such transport. It turns out that the fate of electric cars is purely urban use. We can add here that hydrogen fueled cars are exactly the same as electric cars. The only difference is in the way the electric motor works. In the first case, it is the charge of the batteries, and in the second case, it is the energy of the chemical reaction of hydrogen decomposition. But filling a tank full of liquid hydrogen doesn't take much longer than a regular tank of gasoline. The only question is the infrastructure.

III. Results

Some cars use solar energy to provide part of their electricity needs. Solar panels are used to power electric motors and charge batteries [3]. They only get energy from the sun during the day.

The following calculation is used when calculating the engine power of an electric car:

Required power:

$N_e = g\eta m\vartheta + C_v F\vartheta^3$, Watt

Where: $g = 9{,}8$ m/сек² - acceleration of free fall;

- η- average rolling coefficient on asphalt;
- m- full mass of the car;
- υ- speed in meters in seconds;
- C_υ- body flow coefficient;
- F- frontal area of the car.

For electric vehicles weighing 2000kg, at a speed of 30 km/h. or 8.3m/sec;

N_e=4072 Watt.

with motor efficiency 0.7, transmission 0.9 (total 0.63), then

$N_{бат}$=N_e / Efficiency=4072 / 0.63=6,4 kW.

Discharge current:

I = N: U = 6400: 100 = 64 amperes; With a battery capacity of 150 Ah, the permissible discharge is 100 A/H, the permissible discharge time is 100: 64 = 1.56 hours or 94 minutes.

The distance from here will be 47 km. By changing the parameters of the battery, we can get the range we want, and the electric car should be as light and small as possible.

Like any technical device, the solar battery has its operational and technical characteristics, which differ for different models and different manufacturers, but with a fairly small discrepancy.

With a solar cell area of about 1.5 m2, the power of the module is about 250 W. A typical solar cell has an efficiency of 16-21%. The service life of such a solar battery is at least 25 years.

IV. Discussion

Apart from the solar panels mentioned above, electric vehicles can be energy efficient by using piezoelectric materials [4]. Piezoelectric materials are materials that generate an electric current when they are mechanically affected, even when raindrops fall on them (Kalbiyev and Jamalova, 2020).

Piezoelectric materials are used to generate electricity using the kinetic energy of raindrops [5]. The physical properties of piezoelectric materials allow them to generate electricity. This feature is known as the piezoelectric effect. When compressive or tensile stress occurs in these materials, an electric field is created in the material and a voltage difference occurs, causing current to flow. The occurrence of this stress difference is due to the asymmetry of the shape of the crystals (cells) of these materials. As can be seen from the figure, a small part of the crystalline form (cell) is positively located as a particle in the center. As shown in Fig. 2, when a certain compressive force is applied, this particle slides in a certain direction, distributing the charge and then creating an electric field. These materials come in different forms. Crystals are the most common, but substances such as plastic and ceramics are also found [6].

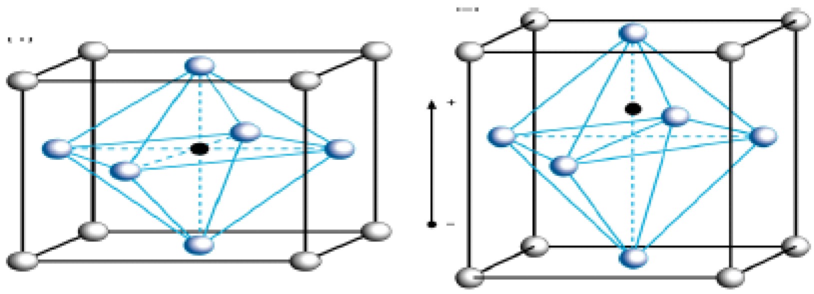

Figure 2: *Structure of the crystal lattice of piezoelectric materials*

The energy obtained by this method is stored in electric batteries and can be used in the electric batteries of electric vehicles.

As shown in Fig. 3, the electrical energy obtained during the use of piezoelectric materials [7] will be directly supplied to the electric battery.

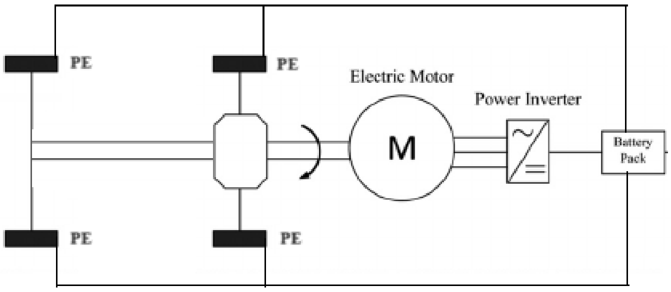

Figure 3: *Power supply and power management of electric vehicles with piezoelectric materials*

The piezoelectric material will be placed on the tires, which can be installed on the wheels, rather than directly on the wheels of the electric vehicle. It is similar to anti-skid pads on car tires. Depending on the amount of electricity consumption of electric machines, the surface area of the piezoelectric material will be determined. During the movement of the electric car, as the piezoelectric materials on the wheels are affected by the car's gravity, as a result, electric energy will be generated, and this electric energy [8] will be transferred to the battery of the electric car.

Figure 4: *Placement of piezo electric material parts on car wheel*

There is experience in using piezo electric materials in cars. There, the piezoelectric material is installed inside the wheel disc. The implementation of this proposal is quite complicated. It interferes with the structure of the disks and changes them. Our proposal does not interfere with the wheel and its other parts. Piezoelectric material parts are installed in a removable cover that is simply attached to the wheel (Fig. 4). One advantage of this offer is that the tire can be fitted to different tire sizes (wheel rims are made for specific tires).

V. Conclusion

One of the main parts of electric cars is its power supply element. Their ability to travel long distances depends on this element. Various methods are proposed to increase this period, for example, installing solar panels. In this paper, another construction for long-distance electric vehicles is proposed. By installing piezoelectric materials in the wheels of electric cars, their long-distance movement is ensured. Unlike electric cars, where solar panels are installed, piezoelectric materials will provide additional electricity at any time when the cars are moving, not just during the day. In electric cars, since piezoelectric materials are installed on the tires, they will not need additional structural changes.

Abstract

The article discusses the issues of the emergence of risks of logistics activities, the nature of their occurrence and the features of technical risks in modern logistics. The classification of risks according to certain signs and the cause of their occurrence is given. The stages of risk management of logistics activities at enterprises of various industries and types of activity are determined. It is determined that one of the main reasons that have increased the possibility of risks in logistics activities is economic instability in the global environment. All this had a negative impact on all areas of business activity, in particular, an increase in the level of uncertainty in the relations of enterprises with counterparties involved in the logistics chain. Possible ways and methods of minimizing the risks of logistics activities are considered, strategies for minimizing risks in the logistics activities of enterprises are recommended.

Keywords: risks, logistics activities, risk management, transport, risk minimization

I. Introduction

The unstable economic situation in the country, caused by sanctions pressure, has had a negative impact on all areas of business activity. Added to this were fluctuations in the foreign exchange market, which contributed to the receivables of many enterprises, which, in turn, led to a reduction in budgets and expenses, and some companies ceased operations altogether.

These changes in the economy have led to an increase in the risks of logistics activities, that is, an increase in deviations from the expected results due to the disruption of the stability of the logistics system of enterprises. Therefore, the issue of reducing risks in the logistics activities of enterprises, taking into account modern economic conditions, is relevant.

The issue of the emergence of risks and the reduction of their impact on entrepreneurial activity is very relevant, especially in the conditions of uncertainty of the external environment, therefore domestic and foreign scientists devote their works to the study of such concepts as "risk", "uncertainty", "methods of assessing the degree of risk", "risk management", etc. S.G. Kholmovsky [6], A.S. Svezhintseva [6], M.I. Raskatova [3], V.I. Sergeev [4] and others.

Various aspects and approaches to the identification and management of risks related to various types of activities are presented in scientific works. However, changes in the external environment, the state of the national economy, changes in the impact of technical risks on logistics activities cause the need for additional research on the issue of reducing the risks of logistics activities in modern economic conditions.

The purpose of the article is to study the technical risks of logistics activities and determine the ways and methods to reduce their impact in modern economic conditions.

II. Methods

In the logistics system, risks occur at almost all stages of the logistics chain, from the supply of raw materials and goods to production and ending with the delivery of finished products to the consumer. The main reasons for the emergence of risks are the uncertainty of external conditions and the instability of the logistics system, including economic, political, currency instability, violation of product delivery times, changes in consumer demand, etc.

There are many definitions of the category of "risk" [1; 5], since this science is quite young. In particular, examples of these definitions are given in the paper [5], but one can agree with the authors regarding their interpretation of the definition: risk can be defined as the possibility of an event that can lead to a disruption of the normal functioning of the logistics system in a constantly changing external environment. This work provides the following reasons for the emergence of uncertainty that causes risks in the logistics system and a decrease in the level of its reliability:

\u2012 randomness, that is, an event that may occur differently in the future;

\u2012 information gap as vagueness and unreliability of information about the environment;

\u2012 a gap in competence, that is, the influence of subjective factors on the result of the analysis of a risk situation;

\u2012 divergence of interests of the parties that are participants in the logistics process;

\u2012 the influence of the internal and external environment on the effectiveness of the logistics system.

Particular attention should be paid to the subjective factors that play a decisive role in the process of risk management in any business activity. It is clear that the functioning of complex systems in a competitive environment, which are logistics systems, is impossible without reliable organizational and managerial elements. Therefore, the priority task of the logistics system is to ensure its reliability by creating a risk management system. Logistics risks are the risks of carrying out logistics operations of transportation, warehousing, cargo handling and inventory management and the risks of logistics management at all levels, including managerial risks arising from the performance of logistics functions and operations [6].

Determining the place of each risk and creating opportunities for the effective application of risk management methods makes it possible to scientifically substantiate the classification of risks, since each type of risk corresponds to a certain method of management.

III. Results

The main reasons for the emergence of logistics risks are limited or lack of information, instability of the external environment, a decrease in the volume of product sales, the likelihood of breaking the contract with the supplier and the carrier, an increase in the level of the customs rate, non-compliance of the selected transport with the requirements of transportation, low quality of carriers' work, imbalance of the main elements of the logistics chain. A detailed analysis of risks according to certain classification features is given in Fig. 1.

To develop effective ways to manage risks in logistics activities, we will consider the risks that may arise in the procurement, production, sales, transport and storage activities of the enterprise.

The following risks are possible within the framework of procurement logistics:

– the risk of delay in the delivery of raw materials or materials to the warehouse due to non-fulfillment of the terms of the contract by the supplier or carrier;

– the risk of damage to raw materials or materials due to non-compliance with the necessary conditions for the transportation and storage of products;

– the risk of an increase in the price of raw materials due to price fluctuations, exchange rate differences or price increases by the supplier;

– the risk of cargo detention at the customs border due to violation of the conditions for certification of goods;

– risk of customs clearance by violation of documentary support of goods.

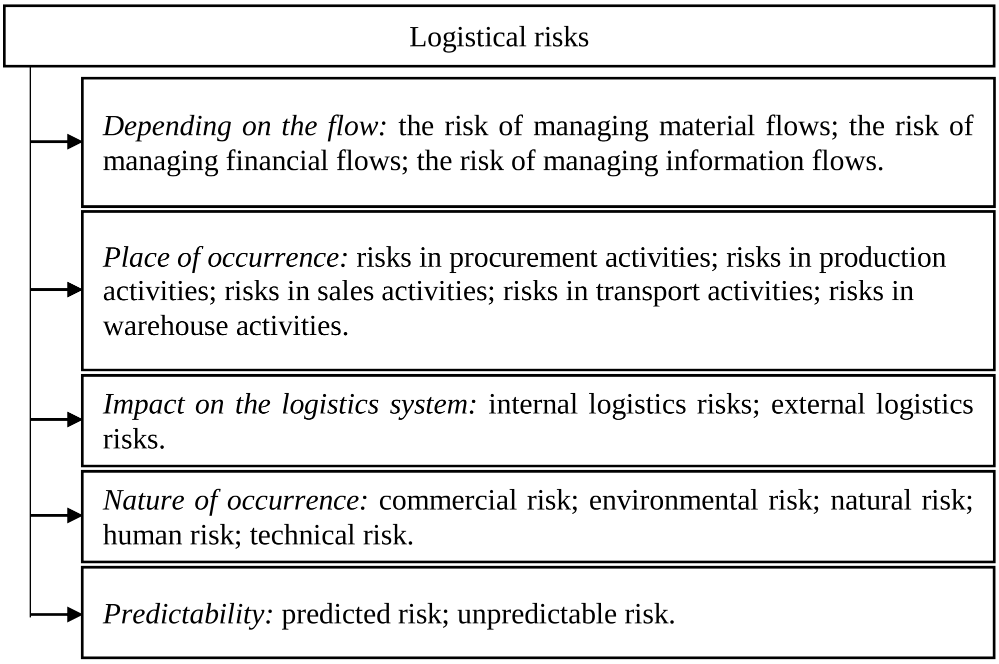

Figure 1: *Classification of risks of logistics activities*

Within the framework of production activities, the following risks are distinguished:

– the risk of a shortage of the required amount of raw materials or materials due to incorrect calculation of the necessary amount of stocks to ensure the uninterrupted operation of the enterprise;

– the risk of an increase in the cost of storing raw materials by raising prices for utilities and renting warehouse space.

Within the framework of sales activities, the following risks are possible associated with the movement and storage of finished products:

– the risk of violation of the deadline for the delivery of products to the customer due to untimely shipment of goods or delay in delivery by the carrier;

– the risk of damage to products during storage and transportation;

– the risk of a surplus or shortage of goods due to an error in determining the optimal amount of demand.

Within the framework of transport activities, we highlight the following risks:

– the risk of severing ties with logistics partners;

– the risk of non-fulfillment of obligations for the transportation of goods by logistics partners;

– the risk of an increase in transportation costs;

– the risk associated with partial damage or complete loss of the goods during their transportation;

– the risk of breakdown of vehicles, which leads to untimely delivery of goods to the consumer.

The following risks may occur within the framework of warehouse activities:

– the risk of an excessive amount of inventory in the warehouse;

– the risk of an expiration date, which will lead to the liquidation of a batch of stock or goods;

– the risk of growth of fixed costs.

Risks in logistics arise in the process of movement of material, financial and information flows, that is, they combine various types of risks of all components of the logistics system. There are the following types of risks of the logistics system:

\u2012 commercial, directly related to the economic aspect of the enterprise's activities;

\u2012 technical, related to the operation of technical means;

\u2012 economic and legal, related to the civil liability of individuals and legal entities in the process of logistics activities;

\u2012 force majeure, which are completely unpredictable.

To reduce the impact of risks on the result of the logistics activities of enterprises, it is important to take into account all aspects of the modern conditions of the logistics activities of enterprises and consider them separately and in interconnection and interdependence.

The following types of risks are considered the most typical in logistics activities:

\u2012 loss of cargo due to theft, false shipment to third parties, damage due to natural and man-made disasters or negative social phenomena;

\u2012 untimely delivery due to delays, changes in routes, etc.;

\u2012 damage to goods, when the use value of goods is lost in whole or in part due to the movement of goods for a long time in long chains of transportation, transshipment, sorting, etc.

\u2012 improper execution of accompanying documents, as a result of which problems arise during customs clearance of goods;

\u2012 disclosure of confidential information, which may lead to a violation of equality in competition;

\u2012 environmental risks may arise as a result of violation of the rules for the transportation and storage of goods, they may harm the life and health of people or the environment;

\u2012 risks of loss of reputation as a result of choosing an unscrupulous partner who may have a negative reputation;

\u2012 risks of civil liability for causing losses to third parties in the process of carrying out logistics operations.

Due to the occurrence of risks, the following types are distinguished:

\u2012 internal risks – organizational, technical and technological, depend mainly on the company's employees. They can be reduced by the correct organization of logistics processes at the enterprise;

\u2012 external risks are those that do not depend on the company at all. These include natural disasters, international conflicts, epidemics. To minimize them, it is necessary to calculate possible scenarios of events on the way of cargo movement;

\u2012 mixed risks - associated with both external factors and the behavior of the company's employees. These include theft, violation of the rules for the transportation and storage of goods, legal and legal risks, financial risks.

In order to reduce risks to a minimum level, to ensure the development of the logistics system and its functioning, it is necessary to manage risks by using appropriate methods. Risk management of the logistics system is a set of methods, functions and stages of the logistics cycle process, the successful application of which allows you to prevent risks or reduce them, ensure the sustainable functioning and development of the logistics system of the enterprise. The risk management process is carried out in stages.

At the first stage, it is necessary to identify the external and internal risks of the logistics system under study. At this stage, risks specific to each specific enterprise are identified and identified.

At the second stage, a qualitative and quantitative assessment of risks is carried out, that is, the amount of losses in the event of a risk event and the probability of its occurrence are identified. At this stage, the statistical method, the method of the stage of expert assessments, the method of analogies are used.

At the third stage, the analysis of the impact of risk factors, its magnitude and frequency on the indicators of logistics activities is carried out using correlation and regression analysis, simulation modeling and analytical methods.

At the fourth stage, it is necessary to carry out forecasting, modeling decisions made to prevent logistics risk;

At the fifth stage, the acceptability of the logistics risk is assessed and the management method that can ensure its minimization is selected.

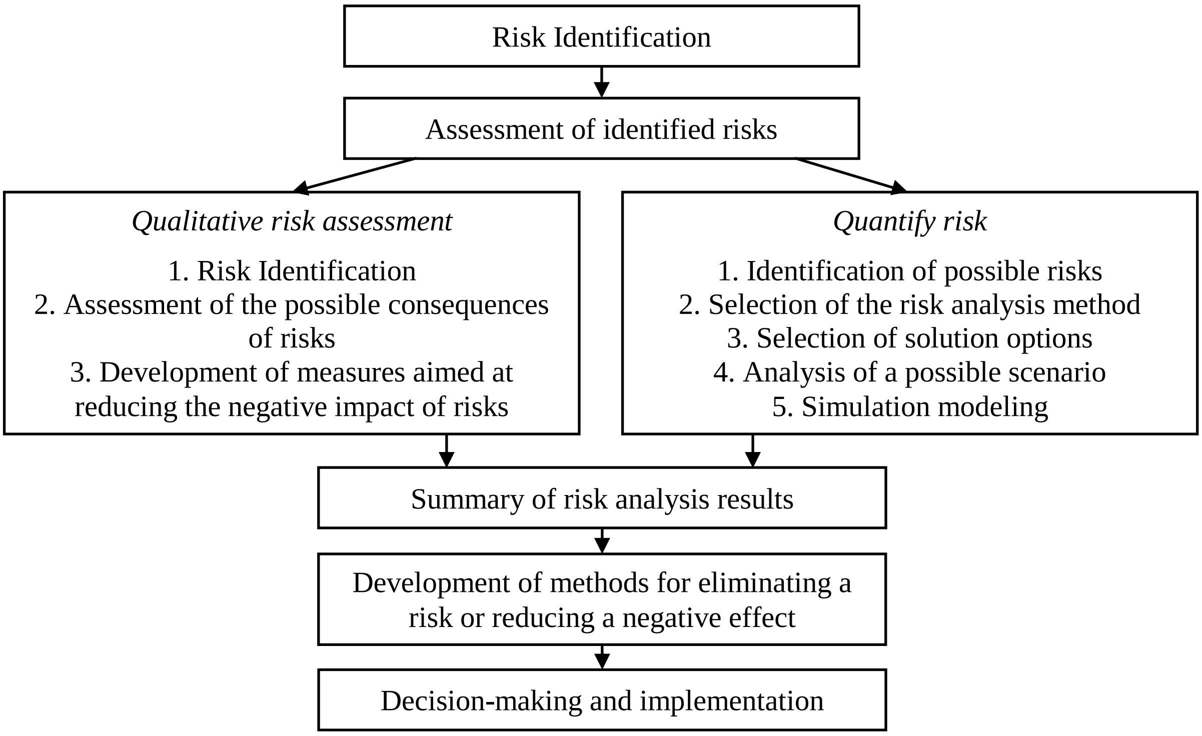

Figure 2: *Algorithm for managing the logistics risks of the enterprise's activities*

Usually, the methods of minimizing risks are: risk avoidance; localization of risks; risk diversification; risk compensation; risk transfer; limitation; insurance [3].

If risk avoidance involves rejection of the services of unknown or dubious partners, rejection of dubious offers, then integration or association with reliable partners allows you to distribute risks between them and reduce the impact of a certain type of risk on each of the parties to the transaction.

To reduce the impact of risks on logistics activities, it is possible to use risk localization methods that provide for local interest - the link in the supply chain that is the most risky.

IV. Discussion

Reducing the degree of risk is also possible through the use of differentiation of activities and/or markets for products with an expansion of the range of products, orientation to various groups of consumers, etc.

Risk compensation provides for the use of strategic planning of enterprises, forecasting the external environment, monitoring the socio-economic and legal environment and creating a system of reserves.

Risk transfer is carried out through the conclusion of lease, supply, storage, transportation, maintenance, etc. agreements.

To reduce the expected risks, it is possible to carry out limitation, that is, to establish maximum costs when selling goods on credit.

At the same time, it is advisable to include the method of risk management, which is relevant in modern economic conditions both for the logistics system and for enterprises of all types of activity, since the instability and uncertainty of both external and internal conditions for the functioning of the economy contribute to an increase in risks at all stages of logistics activities. Such a method is the method of risk acceptance, that is, readiness for risk and the formation of measures that can prevent foreseeable losses. In this case, management decisions should be aimed at forming readiness for their occurrence through the creation of self-insurance and external insurance funds.

Insurance is the main and more widespread way of minimizing risks, which is used by both manufacturers and carriers on domestic flights and international carriers. One of the ways to manage logistics risks is the Incoterms 2020 rules, which are eleven unified rules applied in the practice of world trade. These rules set out the rights and obligations of the parties to a foreign trade contract in terms of the supply of products from the seller to the buyer [2]. These rules regulate both the distribution of transportation costs between the seller and the buyer, and the transfer of transport risks (damage to goods, loss or unexpected destruction of cargo) and insurance.

Risk management in the logistics system is closely related to the chosen corporate strategy, which ensures its stability and effective operation. The work [4] reflects the influence of the enterprise strategy on the choice of risk management methods in the logistics systems of the enterprise:

When choosing a "cautious" strategy, the company can abandon logistics risks or transfer it to another participant in the logistics process. A "balanced" strategy involves, depending on the current situation, the assumption of risk and the creation of insurance funds or the provision of guarantees, the transfer or rejection of logistics risks. A "risky" strategy may involve accepting or transferring risks depending on the specific situation.

In modern conditions of economic development, enterprises are faced with the need to search for methods to expand the sales market by entering international markets. In these conditions, risk becomes an integral condition for the functioning of the enterprise due to the effect of economic, financial, legal and political factors, which often generate various threats of material losses in the implementation of foreign economic activity. In addition, enterprises are increasingly making management decisions in conditions of uncertainty, so the issue of logistics risk management at enterprises focused on foreign markets requires special attention.

All components of the risk management process are closely interrelated, and each has not only a determining, but also a subordinate nature in relation to the other component. The multi-stage nature of the logistics system implies a high level of potential risk. Therefore, the logistics system should provide for a set of measures aimed at maintaining a high level of reliability of the system, which should minimize the probability of adverse events, from the point of view of risk management.

Thus, for the effective functioning of the logistics system in conditions of uncertainty, it is necessary to assess and analyze the risks of logistics activities. The use of the proposed methodological approaches to logistics risk management will make it possible to identify reserves for improving the efficiency of managing individual business processes of the logistics system and develop measures aimed at optimizing costs, using the resources of logistics system participants in the most rational way and meeting the requirements for the quality of logistics services in the supply chain.

THE IMPACT OF DIGITAL TECHNOLOGIES ON SUSTAINABLE CONSUMPTION AND PRODUCTION

Ermolovskaya Olga

•

Financial University under the Government of the Russian Federation, RUSSIA
ermoy@mail.ru

Abstract

The article explores the transformative role of digital innovations in advancing sustainability across industries. It focuses on how technologies such as artificial intelligence (AI), the Internet of Things (IoT), blockchain, and big data analytics are reshaping the way businesses and consumers interact with resources, leading to more sustainable consumption and production models. These technologies help optimize resource use by improving the efficiency of supply chains, enhancing waste management systems, and enabling real-time monitoring of environmental impacts. For instance, AI and machine learning algorithms allow companies to forecast demand more accurately, reducing overproduction and minimizing waste. IoT devices provide valuable data on energy and resource consumption, enabling more efficient production processes, while blockchain ensures transparency and traceability in supply chains, helping consumers make informed, sustainable choices. The article also examines the growing influence of digital platforms that promote sustainable consumption, such as apps encouraging eco-friendly purchasing decisions or online marketplaces for sharing and reusing goods. By leveraging data-driven insights, these platforms encourage consumers to adopt sustainable lifestyles, while businesses can better align their operations with sustainability goals. Additionally, the article delves into the potential for digital technologies to accelerate the transition to a circular economy, where products and materials are reused, repaired, and recycled instead of following a linear lifecycle. However, the article also addresses the challenges and limitations of adopting digital technologies for sustainability. These include concerns over data privacy, the energy consumption of digital infrastructures, the need for standardized regulations, and the widening digital divide that could limit the accessibility of these technologies in certain regions. Despite these hurdles, the potential of digital technologies to revolutionize sustainable consumption and production is immense, offering new pathways to achieve global sustainability targets and reduce environmental degradation.

Keywords: circular economy, resource optimization, waste management, real-time monitoring

I. Introduction

In the modern era, digital technologies are playing an increasingly pivotal role in transforming industries and reshaping how societies consume and produce goods. As the global community faces growing environmental challenges—such as climate change, resource depletion, and waste accumulation—there is an urgent need to shift towards more sustainable models of consumption and production. Sustainable Development Goal 12 (SDG 12), established by the United Nations, emphasizes the importance of responsible consumption and production patterns to ensure the long-term well-being of both people and the planet.

In this context, digital technologies like artificial intelligence (AI), the Internet of Things (IoT), blockchain, and big data analytics are emerging as powerful tools for fostering sustainable practices. These technologies offer unprecedented opportunities to enhance efficiency, reduce waste, and create transparency across supply chains, which are critical in promoting sustainability across various sectors.

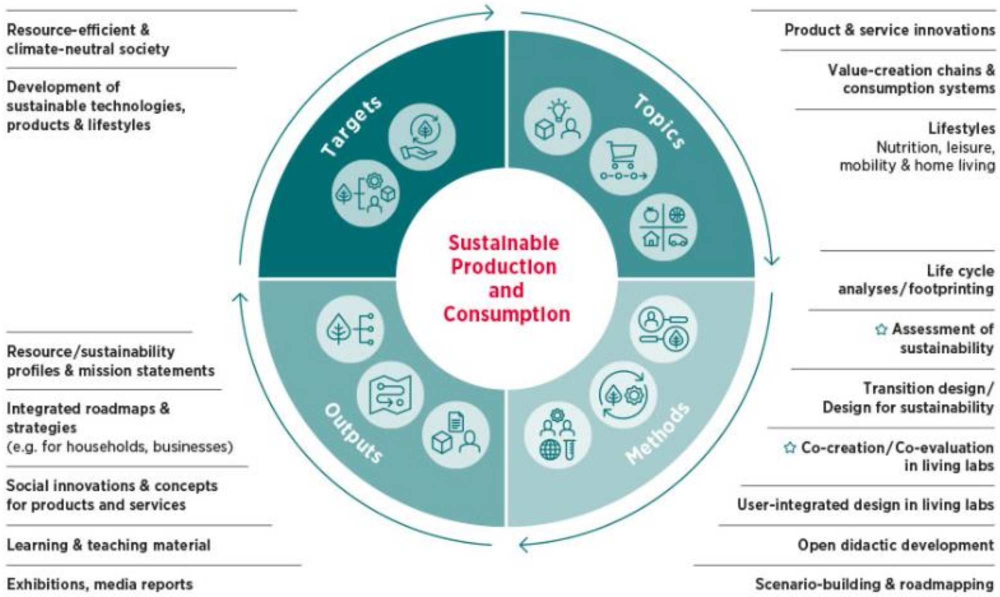

Figure 1: *Sustainable Production and Consumption Division analyses*

To create a climate-neutral and resource-efficient society in the medium to long term, it is essential to undertake a fundamental "dematerialization" of production and consumption. This involves implementing strategies focused on efficiency, consistency, and sufficiency, which ensure that products are designed to be "lighter on resources" and can be utilized for longer periods and in more effective ways. The process of achieving this is inherently tied to thoughtful design.

The Sustainable Production and Consumption Division is dedicated to analyzing, evaluating, and developing technological and social innovations through the use of real-world laboratories and living labs. These environments actively involve users in the development process, both before and during innovation implementation. Researchers assess the resource efficiency and social impacts of production and consumption along value chains, creating transformative approaches and scenarios that aim for climate neutrality, resource efficiency, and sustainability. Their focus areas include nutrition, leisure, mobility, and housing.

For meaningful changes in production and consumption patterns to take place, it is crucial to have companies that create and provide these innovative products and services. Additionally, empowered consumers who actively utilize these offerings are necessary, along with a supportive political framework that facilitates the transformation process.

The research undertaken by the Sustainable Production and Consumption Division encompasses several key areas:

- Sustainability and Resource Assessment: Evaluating the sustainability of materials and processes.
- Product and Service Innovations: Developing new offerings in real-world laboratories and living labs that prioritize sustainability.
- Education: Fostering knowledge and awareness around sustainable practices among consumers and businesses.
- Science-Based Innovation, Enterprise, and Consumer Policy Approaches: Informing policies that support sustainable production and consumption.

This research is characterized by its inter- and transdisciplinary nature, leveraging collaborations across numerous national and international networks. The Division draws upon extensive experience from various third-party funded projects, enhancing its ability to drive forward the agenda of sustainable production and consumption.

The integration of these digital innovations is not just limited to businesses optimizing their production processes but also extends to consumers who are becoming more empowered to make eco-friendly choices. Digital platforms are facilitating access to information, enabling consumers to adopt sustainable lifestyles, while businesses are using real-time data to reduce their environmental footprint.

However, while digital technologies present immense potential for advancing sustainability, their implementation comes with challenges. Issues such as the energy consumption of digital infrastructures, data security, and the need for comprehensive regulations to govern digital ecosystems must be addressed to ensure that these technologies contribute meaningfully to sustainable development.

This paper aims to explore how digital technologies are impacting sustainable consumption and production, highlighting both the opportunities they offer and the obstacles that must be overcome to harness their full potential.

Demographic shifts, including population growth and rapid urbanization, are intensifying pressure on existing food systems and agricultural resources. As global food demand rises, there is an urgent need for sustainable practices to ensure food security while safeguarding the environment. Additionally, the ongoing effects of climate change further strain the availability and quality of essential resources for agriculture, underscoring the importance of adaptation and innovation in food production. These complex challenges demand integrated, forward-thinking approaches to achieve sustainability in food systems, requiring transformative changes across agricultural practices.

A key aspect of this transformation involves the evaluation and adoption of advanced production technologies, which can help drive sustainable productivity growth. These technologies also hold potential for influencing broader trends, such as sustainable consumption patterns and reductions in greenhouse gas (GHG) emissions.

Digital technologies, including artificial intelligence (AI), big data (BD), the Internet of Things (IoT), and cloud computing (CC), are increasingly recognized as vital tools for addressing sustainability challenges in food systems. These technologies can enhance supply chain transparency and efficiency, reduce food loss and waste, and optimize resource use. For example, automation can streamline production processes, while biotechnologies can improve crop resilience and quality, essential for maintaining sustainable production in the face of climate change. Furthermore, digital innovations can optimize transportation and logistics, lowering carbon footprints and minimizing environmental impacts across the food supply chain.

Investment in research and development of digital technologies could yield significant benefits, particularly in promoting sustainable food systems globally. However, fully realizing the potential of these technologies requires not only technical innovation but also increased awareness, understanding, and adoption by all stakeholders in the food supply chain.

This paper seeks to explore the broader impact of digital technologies on sustainable food production and consumption. Specifically, it aims to assess how these innovations affect municipal waste, primarily stemming from food consumption, and agricultural emissions of nitrogen and methane, which are key contributors to GHG emissions. Additionally, the study aligns with the objectives of Sustainable Development Goal 12 (SDG12), which focuses on promoting responsible consumption and production patterns.

Despite the growing importance of digital solutions in agriculture, research gaps remain, particularly in the form of detailed longitudinal analyses that track the long-term impact of digital technologies on food sustainability. There is also a need for a more comprehensive understanding of the intricate relationships between food production, consumption, and critical variables tied to sustainability.

The originality of this study lies in its application of Structural Equation Modeling (SEM) to assess correlations between the adoption of digital technologies and key sustainability metrics, particularly in relation to food production and consumption. By offering valuable insights into how these technologies can mitigate food waste and agricultural emissions, this research aims to contribute to the development of policies and practices that foster long-term food sustainability.

The structure of this paper includes six sections: an introduction outlining the research purpose and objectives, a literature review and hypothesis development, a description of the research methodology, presentation of the findings, discussion of the results, and conclusions summarizing the key contributions of the study.

II. Methods

This section outlines the research design, data collection, and analysis methods used to assess the impact of digital technologies on sustainable food production, consumption, and related sustainability metrics. The study primarily focuses on exploring the correlations between digital technology adoption and key variables such as municipal waste, greenhouse gas (GHG) emissions from food production (specifically nitrogen and methane emissions), and overall progress towards Sustainable Development Goal 12 (SDG12), which promotes responsible consumption and production.

1. Research Design

This study employs a mixed-methods approach, combining quantitative data analysis with qualitative insights to understand the multifaceted impact of digital technologies on food sustainability. The research was designed to capture both the breadth and depth of technological influences across the food supply chain, from production to consumption.

Structural Equation Modeling (SEM) was chosen as the primary analytical tool to assess the relationships between digital technology adoption and sustainability outcomes. SEM allows for the testing of complex relationships between observed and latent variables, making it well-suited for evaluating the multi-dimensional effects of digital technologies on food systems.

2. Data Collection

The study utilized secondary data sources for quantitative analysis, including data from international organizations, government reports, and industry publications. These data sources provided information on the following variables:

- Adoption of digital technologies: Data on the implementation of AI, Big Data, IoT, and cloud computing in agricultural and food supply chain processes were gathered from industry reports and technology adoption studies.
- Municipal waste: Data on food waste at the municipal level, particularly in urban areas, were sourced from reports by the United Nations Environment Programme (UNEP) and the Food and Agriculture Organization (FAO).
- Agricultural GHG emissions: Data on nitrogen and methane emissions from agriculture were obtained from reports by the Intergovernmental Panel on Climate Change (IPCC) and national greenhouse gas inventories.
- Sustainable Development Goal 12: Indicators related to SDG12 were collected from the United Nations' Sustainable Development Goals (SDG) database, focusing on responsible consumption and production patterns, particularly those tied to food systems.

In addition, qualitative data were collected through interviews with industry experts, technology providers, and stakeholders in the food supply chain, including farmers, food processors, retailers, and policymakers. These interviews provided insights into the practical challenges and opportunities of implementing digital technologies in real-world settings.

III. Data Analysis

The analysis followed a two-step process:

A. Quantitative Analysis using Structural Equation Modeling (SEM)

SEM was used to test the hypotheses on the impact of digital technologies on sustainable food production, consumption, and waste reduction. This method allowed for the examination of both direct and indirect effects of technology adoption on food sustainability metrics. Key steps in the SEM analysis included:

1. Model Specification: A conceptual model was developed to represent the hypothesized relationships between digital technology adoption, food waste reduction, GHG emissions, and SDG12 indicators.
2. Model Estimation: Maximum likelihood estimation (MLE) was used to estimate the parameters of the SEM model.
3. Model Fit Assessment: Goodness-of-fit indices, such as the Chi-square test, Comparative Fit Index (CFI), and Root Mean Square Error of Approximation (RMSEA), were used to evaluate the model fit.
4. Hypothesis Testing: The relationships between variables were tested for significance using standard error estimates and p-values.

B. Qualitative Analysis

A thematic analysis of interview data was conducted to complement the quantitative findings. Key themes included:

- Barriers to technology adoption: Challenges faced by stakeholders in integrating digital solutions into their operations.
- Opportunities for sustainability: Insights into how digital technologies can contribute to improved resource efficiency, waste reduction, and sustainable practices.
- Policy and regulatory support: The role of governments and international organizations in facilitating or hindering the adoption of sustainable technologies.

4. Hypotheses Development

Based on the literature review and theoretical foundations, several hypotheses were developed to guide the research. These hypotheses included:

- H1: The adoption of digital technologies (AI, Big Data, IoT, CC) in the food supply chain positively correlates with a reduction in municipal food waste.
- H2: Digital technologies in agriculture contribute to the reduction of nitrogen and methane emissions, improving agricultural sustainability.
- H3: Digital technologies in food systems positively impact the achievement of Sustainable Development Goal 12 by enhancing sustainable consumption and production patterns.
- H4: The effect of digital technologies on food sustainability is mediated by improved supply chain transparency and collaboration among stakeholders.

5. Limitations

Several limitations should be acknowledged in this study. First, reliance on secondary data may present challenges regarding the consistency and accuracy of the data, as reporting practices vary across sources. Second, the cross-sectional nature of the quantitative data limits the ability to draw conclusions about long-term trends. Future research could benefit from longitudinal studies that track the impact of digital technologies over time.

In summary, the methods employed in this study, including SEM and qualitative interviews, provide a comprehensive framework for assessing the impact of digital technologies on food sustainability, focusing on critical variables such as municipal waste, GHG emissions, and progress towards SDG12. The combination of quantitative and qualitative data ensures a robust understanding of the challenges and opportunities presented by digital innovations in the food sector.

IV. Results

The use of digital technologies in agriculture can have a significant impact on the efficiency and sustainability of food systems. However, for these technologies to achieve a truly transformative effect, their implementation must consider the social, economic, and cultural contexts of the communities in which they are used. Improving access to food and reducing the carbon footprint of global agri-food systems are critical priorities for achieving Sustainable Development Goals (SDGs) and ensuring global food security.

The primary objective of this study was to explore the impact of digital technologies on food production and consumption, with a particular focus on their influence on municipal waste, largely originating from food consumption, nitrogen and methane emissions from agriculture, and sustainable consumption and production in alignment with SDG12. The study utilized longitudinal data to track trends over time, offering insights into how these technologies affect sustainability in the food sector. Additionally, it examined the relationships between agricultural production, waste generation, and greenhouse gas (GHG) emissions to better understand the complex interactions in the food supply chain.

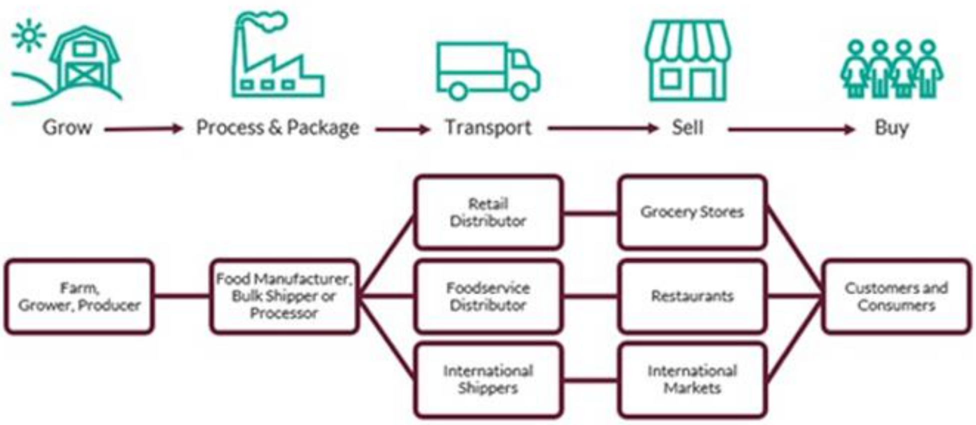

Figure 2: *The Global food supply chain*

Food supply chains represent one of the most significant yet underappreciated areas for investment and business innovation. This industry impacts every individual globally and stands at the precipice of disruption.

In the medium term, the future of food supply chains will revolve around assembling a network of resilient suppliers capable of providing year-round harvests, with inputs sourced from around the globe. The long-term outlook is even more promising, especially with emerging technologies guiding us toward a post-carbon future. For instance, "touchless agriculture" is one of the transformative technologies on the horizon, utilizing extensive data analytics to help farmers select optimal seeds without the need for physical planting, potentially revolutionizing agricultural practices.

The global food supply chain plays a critical role in transporting, processing, and marketing food worldwide. Globalization has facilitated this process, enabling food chains to deliver substantial quantities of quality products to nourish approximately one in nine people on Earth. However, globalization should not be viewed solely from an economic standpoint; its social and environmental implications are equally important.

While globalization enhances the availability of quality foods and fosters advancements in agricultural techniques and transportation, it also poses sustainability challenges. The environmental and cultural impacts of global food chains cannot be overlooked. For example, the globalization of food production can lead to job losses in specific regions due to outsourcing and shifts in transportation practices. It has contributed to enhanced food security but simultaneously raised concerns regarding food safety.

Moreover, global food chains have induced considerable ecological disturbances at local, regional, and even international levels. Although globalization brings numerous advantages, it also carries side effects that often go unnoticed or unaddressed.

Given that globalization is a persistent reality, food supply chains must take proactive measures to ensure their long-term sustainability. This requires a holistic approach that balances economic growth with environmental stewardship and social responsibility, ensuring that food systems remain resilient and equitable for future generations. Embracing sustainable practices within global food chains will be essential for mitigating adverse effects while maximizing the benefits of globalization.

The key findings of the study revealed several important points. First, there is a negative relationship between digital technologies and SDG12, indicating that while these technologies can have a positive effect on sustainability, their overall impact on consumption and production is moderate but significant. This supports the H2 hypothesis, suggesting that the application of digital technologies may have unintended consequences for sustainable development. The study also found that increasing efficiency through digital tools can paradoxically lead to higher resource consumption.

The study also highlighted the challenges posed by digitalization in agriculture. As Kamble et al. pointed out, these include ensuring equal access to technology and data for all stakeholders, particularly smaller producers, as well as addressing concerns around data protection and cybersecurity in increasingly complex and interconnected food supply chains. Despite these challenges, the research confirmed a positive relationship between agricultural production and both sustainable consumption and the generation of municipal solid waste, validating the H1 and H3 hypotheses. This finding emphasizes the close connection between agricultural productivity and sustainability, as increased production brings both benefits and challenges for waste management.

Moreover, the study demonstrated that digital technologies can play a crucial role in reducing municipal solid waste by optimizing various processes such as production, distribution, and inventory management. This finding, which aligns with the research of Bahn et al., validates the H4 hypothesis, showing that digital tools can contribute to more effective waste management and, in turn, support the sustainability of food systems. However, the study also stressed the importance of considering the indirect environmental impacts of digital technologies, such as increased energy consumption and the generation of electronic waste. These factors must be managed carefully to ensure that the sustainability benefits of digitalization in agriculture are not undermined.

In conclusion, the study highlights the dual nature of digital technologies in the agricultural sector. While they offer significant potential to reduce waste, improve supply chain efficiency, and contribute to sustainable food production, they also present risks related to increased energy consumption and unequal access. As a result, a balanced and cautious approach to the implementation of these technologies is essential to ensure they contribute positively to the long-term sustainability of food systems.

IV. Discussion

I. Subsection One

The findings of this study indicate that sustainable consumption and production practices, in alignment with Sustainable Development Goal 12 (SDG12), have a negative influence on greenhouse gas (GHG) emissions from agriculture, supporting the H5 hypothesis (fig.3). This result highlights the critical role that sustainable practices can play in reducing agricultural emissions and mitigating environmental impact. These findings are consistent with the research of Dong et al., Agrawal et al., and Sharma et al., who emphasize that companies can enhance their operational efficiency using digital technologies while contributing to sustainability efforts, particularly in achieving SDG12. By improving efficiency and reducing GHG emissions, digital technologies can strengthen the sustainability of supply chains, making them more transparent and accountable. Furthermore, these technologies facilitate the monitoring and reporting of sustainable practices, thereby reinforcing sustainability goals across industries.

The study also confirmed the H6 hypothesis, revealing a positive relationship between agricultural production levels and GHG emissions. This suggests that as agricultural production increases, so too do emissions, underscoring the urgent need for more sustainable agricultural practices to reduce environmental degradation. Research by Kabange, Xu, Wang, and Ouyang supports these findings, showing that agriculture is a significant source of global GHG emissions due to activities like livestock fermentation and fertilizer use. However, modern agricultural practices, coupled with the adoption of digital technologies, can help mitigate these emissions by enhancing efficiency and sustainability.

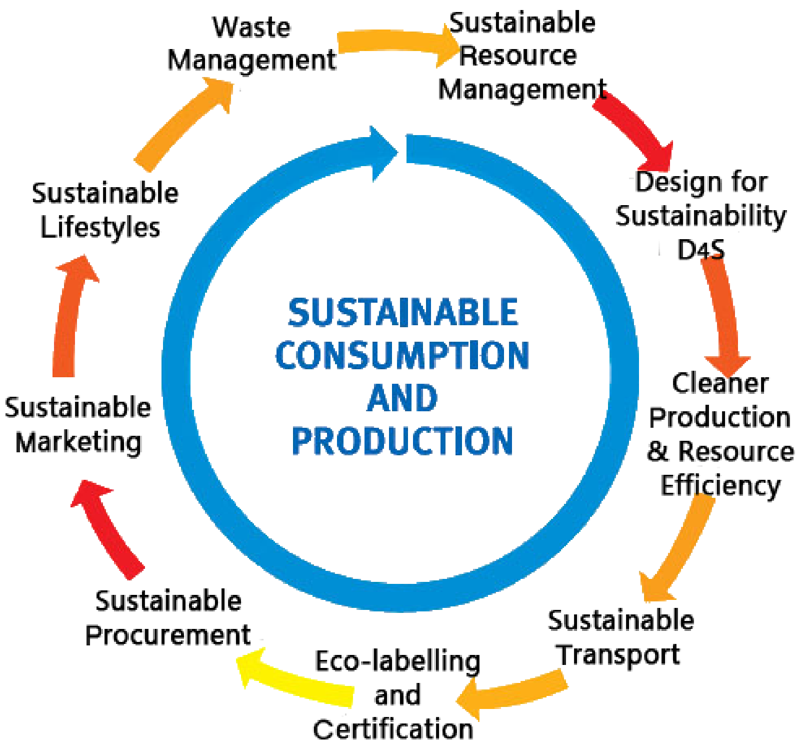

Figure 3. Sustainable consumption & production

Digital technologies, when implemented in agriculture, can provide significant advantages, including better resource management, real-time decision-making tools, and more sustainable farming practices. The results highlight the importance of promoting the adoption of these technologies across the food supply chain to meet sustainability goals. However, challenges remain, particularly regarding the equitable access to these technologies, especially for small- and medium-sized primary producers. Investments in digital infrastructure and education are necessary to support the transition to more efficient and sustainable agri-food systems.

The European Union (EU) is taking a proactive stance in promoting the digitalization of agriculture as part of its efforts to transition to more sustainable farming practices. The concept of the "fourth agricultural revolution" emphasizes the potential for digital technologies to transform agriculture radically. By integrating these technologies, production processes and resource management can be optimized, enhancing sustainability and resilience in the face of current and future challenges.

Digital technologies offer numerous benefits to agriculture, such as increased efficiency, reduced environmental impact, improved food quality, and higher incomes for producers. These tools also support more sustainable farming practices by reducing reliance on external inputs like pesticides and chemical fertilizers, while promoting the efficient use of natural resources. Additionally, they enhance access to agricultural information and services, particularly for rural producers, fostering greater transparency and efficiency across the entire food supply chain.

However, despite the advantages of digitalization, there are significant barriers to its widespread adoption. The high cost of advanced agricultural technologies can be prohibitive for primary producers, particularly in developing countries. Furthermore, a lack of training and resources to support the adoption of these technologies may exacerbate existing inequalities, creating a digital divide within the agricultural sector. Therefore, efforts to promote digitalization must address these challenges to ensure that the benefits of technology reach all stakeholders and contribute to the broader goal of sustainable development.

II. Subsection Two

The challenges facing food systems are multifaceted and interconnected, reflecting the complexity and fragility of the global food chain. Issues such as population growth, competition for resources, climate change, dietary shifts, limited food access, unsustainable agricultural practices, and significant food waste contribute to the precariousness of food security. Rapid urbanization and population expansion place immense pressure on natural and agricultural resources, increasing the risks of food insecurity and environmental degradation. Climate change exacerbates these problems by directly impacting agricultural productivity and food accessibility for millions worldwide. Unsustainable farming methods further highlight the urgent need for reforms in agricultural and food supply chains to promote more equitable and sustainable production and consumption practices.

Reducing food waste and improving access to nutritious, sustainable food are essential to achieving future food security and sustainability. A sustainable food system benefits not only human health by ensuring access to safe, healthy food but also the environment and economies by protecting natural resources and supporting agricultural communities. As agriculture is a fundamental part of global economies and livelihoods, efficient and sustainable agricultural practices are critical to minimizing the sector's environmental footprint. The current production and consumption patterns exacerbate climate change through increased greenhouse gas (GHG) emissions, highlighting the need for more environmentally friendly agricultural practices that protect future generations.

This paper emphasizes the role of digital technologies in optimizing resource use and reducing environmental impacts, fostering more sustainable consumption and production patterns. Additionally, these technologies can mitigate municipal waste by improving resource management. However, without appropriate regulations and sustainable resource management strategies, the use of these technologies could lead to resource overuse, necessitating a balanced approach to their implementation. To fully harness the benefits of digital technologies, legislative and policy frameworks must evolve in tandem with technological advancements, facilitating widespread adoption in agriculture beyond the food industry.

Understanding the needs and perspectives of primary producers is also essential to developing digital solutions that support a more efficient and inclusive transformation in agriculture. Despite the paper's efforts to explore the relationships between digital technologies, sustainable food production, GHG emissions, and municipal waste, certain limitations exist. The longitudinal nature of the study, while tracking trends over time, may have been influenced by contextual factors or unforeseen events. Additionally, the study focused primarily on the relationship between digital technologies and key aspects of food sustainability, such as crop and animal output, municipal waste, nitrogen and methane emissions, and Sustainable Development Goal 12 (SDG12). Future studies should consider broader aspects of food sustainability, including the social and economic impacts of technological shifts, such as employment in agricultural labor, market access for small producers, or the equitable distribution of technological benefits.

Another important area for future research is the unintended consequences of digitalization in agriculture. While the benefits of digital technologies are substantial, their potential negative impacts, such as the risk of digital exclusion or the concentration of economic power among large corporations, must also be examined. Future studies could investigate the specific effects of emerging digital technologies, including the Internet of Things (IoT), data analytics, and artificial intelligence (AI), on the sustainability of food systems. Such research would provide a more comprehensive understanding of how these technologies can be leveraged to enhance food system resilience while avoiding potential drawbacks.

Abstract

A distorted date of a document is a factor of strong social and public risks, leading to erroneous court decisions and undermining confidence in the judicial system as a whole. Document forgeries are common in the public relations sphere. Often, at the workplace, employees may encounter so-called "black accounting". If the employer provides them with a date issued "retroactively", then there is a possibility of evading criminal liability. The most popular category are bankruptcy cases (about 40% in total). The next are cases on collection of penalties, debt (8%), followed by cases with share of 5% on invalidation of tax authority decisions; on collection of unjust enrichment, etc. Chromatographic methods, most often used in methods for determining the age of a document. Almost all researchers, by default, assume that the components of the writing materials evaporate, and the main factors limiting this process are temperature and illumination.
In spite, the authors suggested that during the storage of documents, not pure components, but their diluted aqueous solutions evaporate. Water is a volatile liquid. The source of this water is the surrounding atmosphere and its good absorbent in the form of paper sheet cellulose.
Another factor of natural aging is the natural drop in atmospheric pressure. In the case of a decrease in atmospheric pressure, the evaporation of aqueous solutions of the components of writing materials should also accelerate.
The number of humidity and pressure cycles was determined based on a decrease in the level of the chromatographic signal of the studied samples. The results presented in our work show that frequent and deep changes in natural humidity and pressure accelerate the evaporation of volatile and soluble components of ink, leading to accelerated aging of the document. Overcoming this problem will help to significantly improve the quality and validity of court decisions in all types of cases under consideration and reduce the risks of obtaining erroneous court decisions.

Keywords: climatic factors, aging of documents, atmospheric pressure, humidity

I. Introduction

Document forgeries are common in the public relations sphere. Often, at the workplace, employees may encounter so-called "black accounting", when the director suggests signing documents "retroactively". When investigating accidents with a fatal outcome or causing serious harm to health, investigative bodies require the issuance of protocols on knowledge testing. If the employer provides them with a date issued "retroactively", then there is a possibility of evading criminal liability. Therefore, it is very common to make a document or make an addition, correction "retroactively".

A distorted date of a document is a factor of strong social and public risks, leading to erroneous court decisions and undermining confidence in the judicial system as a whole.

To compile the most complete picture of the categories of cases, in the resolution of which an examination of the limitation period of the application of document details is carried out, a small table can be shown.

Table 1: *Categories of cases, in which an examination of the limitation period of a document is most often required.*

Court cases	number of cases	%
on bankruptcy of an individual	9	24%
on bankruptcy of a legal entity	6	16%
on collection of penalties, debt for undelivered goods	3	8%
on invalidation of a tax authority decision	2	5%
on collection of unjust enrichment, interest for the use of other people's money	2	5%
on invalidation of transactions	2	5%
on invalidation of a contract for work	2	5%
on invalidation of a pledge agreement	1	3%
on termination of a purchase and sale agreement	1	3%
on invalidation of a surety agreement transaction	1	3%
on recognition of ownership of real estate	1	3%
on bankruptcy of an individual entrepreneur	1	3%
on invalidation of an interest-free loan agreement	1	3%
on invalidation of a purchase and sale transaction for non-residential premises	1	3%
on exclusion from the composition of participants in a limited liability company	1	3%
on collection of debt, penalties under a purchase and sale agreement	1	3%
TOTAL	**37**	**100%**

The most popular category are bankruptcy cases (about 40% in total). The next most popular category are cases on collection of penalties, debt for undelivered goods (8%), followed by cases with the same share of 5% on invalidation of tax authority decisions; on collection of unjust enrichment, interest for the use of other people's money; on invalidation of transactions; on invalidation of a contract for work. Chromatographic methods, most often used in methods for determining the age of a document, demonstrate high dispersion of results and not always satisfactory convergence. Almost all researchers, by default, assume that the components of the writing materials evaporate as a result of evaporation, and the main factors limiting this process are temperature and illumination. Some works compare the influence of abstract factors of natural and artificial aging on the measurement results [1-5]. The authors of [6] were the first to suggest that such an opinion is erroneous. The temperature factor, of course, affects the rate of degradation of the writing composition, although in natural conditions of room storage its fluctuations usually do not exceed several degrees. Light exposure, as a rule, is also limited by the dark conditions of storing documents in folders and cabinets. However, in some cases, the amount of 2-phenoxyethanol in the process of chromatographic analysis begins to increase over time according to chromato-mass spectrometry data [7]. This phenomenon is difficult to explain by temperature or light fluctuations. An alternative hypothesis explaining this fact is the underestimation of such an important factor of natural aging, which, according to the authors, should be changes in atmospheric humidity [6]. This reasoning arose in connection with the fact that, having compared data on the volatility of glycerin and 2-phenoxyethanol, the authors [6] drew attention to the fact that both components are absolutely non-volatile substances, have very high boiling points (240-290 C), very low equilibrium vapor pressures, especially glycerin, which is one of the most non-volatile liquids in nature, and 2-phenoxyethanol at room temperature, according to some data from open sources, is a crystalline substance at 26 C, according to others - at 13 C. [8]

In [6] it was suggested that during the storage of documents, not pure components, but their diluted aqueous solutions evaporate [9]. Unlike 2-phenoxyethanol and glycerol, water is a volatile liquid. The source of this water is the surrounding atmosphere and its good absorbent in the form of paper sheet cellulose [10]. In this case, the natural aging period of the ink will be determined not so much by the duration and temperature of storage, but by the frequency and depth of changes in natural atmospheric humidity. This assumption explains the non-monotonic behavior of the time dependence of 2-phenoxyethanol [7]. During periods of high humidity, a larger amount of easily evaporating 2-phenoxyethanol aqueous solution is formed.

Another factor of natural aging that has not been covered by systematic research is the natural drop in atmospheric pressure. In the case of a decrease in atmospheric pressure, the evaporation of aqueous solutions of the components of writing materials should also accelerate. Considering the above assumption that the components of the writing composition evaporate as part of diluted aqueous solutions, the factor of pressure drops can seriously affect the rate of ink degradation. Pressure and humidity, in contrast to elevated temperature and intense light radiation, represent a separate group of natural climatic factors that do not have a destructive effect on the paper base of the document and on the ink dyes. In this regard, the authors [6] propose to introduce the concept of "accelerated" aging along with the concepts of "artificial" and "natural" aging. This is aging caused by increased exposure to climatic factors during the storage of the document and does not cause the destruction of paper and writing materials.

II. Experimental procedure

Randomly selected writing compositions of both certain brands and unknown brands were used for the study.

Chromatographic and chromatograph mass spectrometric studies were performed on a Crystal-5000 GCMS complex with a flame ionization detector (FID) and a mass detector (MS). Samples were introduced using a pyrolytic attachment (in the case of MS) and a solid sample dispenser in the case of FID. The MS channel is equipped with a device for cryofocusing of gas mixture components. The study was conducted using CR-5 chromatographic columns 30 m x 0.32 mm x 0.5 μm for FID and CR-5 ms 30 m x 0.32 mm x 0.25 μm for MS. Components were identified based on the results of GCMS measurements in the Chromatec Analytic and NIST libraries. The modeling of humidity processes was carried out in a climatic chamber "heat-humidity" M 0/100-1000 KTV in the range of maintaining humidity from 40% to 80%, at a temperature of +25 °C (accuracy of humidity control: 3%. , temperature ± 5 C). The choice of the humidity range was determined by typical differences for the city of St. Petersburg.

During one cycle of studies, samples of strokes applied to office paper were kept for 3 hours in a climatic chamber at a relative humidity of 80%, then 3 hours at a humidity of 40% or natural drying in the air for 24 hours.

The number of humidity cycles was determined based on a decrease in the level of the chromatographic signal of the studied samples to background values or until reaching a horizontal plateau.

Detection of signs of accelerated aging of documents was carried out using GCMS measurements, and optical microscopy using a MIKMED-6 microscope with a built-in web camera. The calculation of the correlation coefficients (Pearson coefficients) of the intensity of the chromatographic response and the number of cycles of humidity changes was calculated using the formula:

$$Rxy = \frac{n\sum_{i=1}^{n} x_i y_i - \sum_{i=1}^{n} x_i \sum_{i=1}^{n} y_i}{\sqrt{\left(n\sum_{i=1}^{n} X_i^2 - \left(\sum_{i=1}^{n} x_i\right)^2\right) \times \left(n\sum_{i=1}^{n} y_i^2 - \left(\sum_{i=1}^{n} Yi\right)^2\right)}} \quad (1)$$

where Xi are the serial numbers of the humidity change cycles, Yi are the corresponding values of the chromatographic peak intensity. The relative dispersion (σ%) of the chromatographic response intensity was calculated using the formula

$$\sigma\% = \frac{\sigma_{a\delta c}}{\bar{y}} \times 100\% \quad (2)$$

where

$$\sigma_{abs} = \sqrt{\frac{\sum(\bar{y}-y_i)^2}{n(n-1)}} \qquad \bar{y} = \frac{\sum_{i=1}^{n} y_i}{n}$$

The pressure drop processes were simulated in a sealed chamber with a volume of 2 liters. The vacuum was created using a diffusion pump H-250/2500 with a depth of up to 0.133 Pa. The duration of one cycle is 24 hours. The number of pressures drop cycles was determined based on the decrease in the chromatographic signal level of the studied samples to background values or until reaching a horizontal plateau. Detection of signs of accelerated aging of documents was performed using GCMS measurements and a MIKMED-6 microscope with a built-in web camera. The dynamics of individual components was studied.

III. Research results

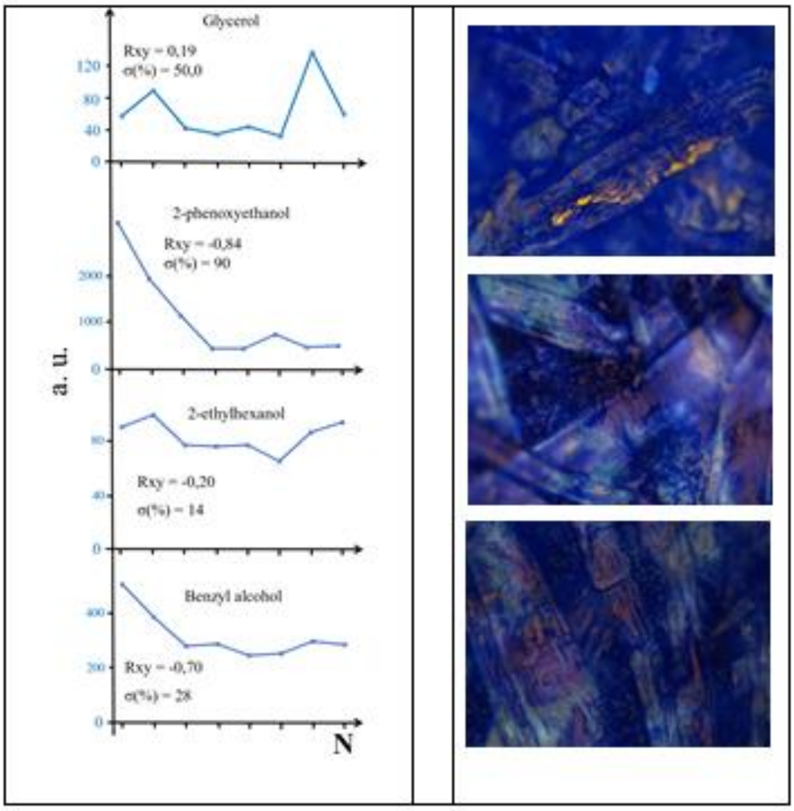
The average results of measuring the GC dynamics of individual components of the writing composition under the influence of humidity changes are given in Table 2. On the right are microscopic images of the surface of the ballpoint ink stroke obtained at the beginning of the process, in the middle and at the end.

The results presented in Table 2 show that periodic exposure of a document to humid air results in strong dispersion of the chromatographic signal. For various ink components and mathematical processing methods, the relative signal dispersion can vary from 18 to 1000 percent or more. The Pearson coefficients of signal intensity change with increasing number of humidity cycles can also be in a wide range from values close to +0.7 to -0.8 or more.

Most of the studied samples demonstrate a consistent decrease in the content of soluble ink components in a stroke with increasing number of humidity change cycles. 2-phenoxyethanol and benzyl alcohol demonstrate a stable dynamics of content decrease in a stroke with increasing number of humidity – drying change cycles. 2-ethylhexanol can react to humidity changes in different directions. Glycerol, in all cases, exhibits strong dispersion of chromatographic peak intensity values and low Pearson coefficient values. In approximately half of the studied cases, for most components, the first wet aging cycle leads to a significant increase in the content of the volatile component in the chromatographic response. Then this content decreases systematically as the number of cycles of drops increases. This behavior of the components strongly resembles the effect noted in [7].

It is evident that artificial modeling of humidity fluctuations in the range of 40-80% leads, in some cases, to accelerated aging of ink according to the criterion of the content of volatile components in it. In other cases, it leads to the appearance of uncontrolled strong fluctuations in the values of chromatographic peaks.

Table 2: *Research of the GC dynamics of individual components of the writing composition under the influence of humidity changes*



The results of the microscopic study show that signs of wet accelerated aging appear on the materials of documents in an implicit form, which does not allow the document to be clearly identified as "artificially aged". There are no areas of melting, bleeding and chipping of the dye, yellowing and uneven fluorescence. This explains some of the anomalies previously discovered by researchers during chromatographic studies of the age of ink [7]. And refutes the opinion about the insignificant influence of the humidity factor on the evaporation rate of high-boiling components of ink [11]. The porous nature of the ink stroke and the paper base on which it is applied results in the penetration of components that are fluid at the time the stroke is applied into the volume of the paper sheet, creating a diffuse region at the paper-stroke boundary. It is obvious that the action of capillary forces causes processes similar to the separation of components of an extract on a thin-layer chromatography plate [12].

The amount and rate of evaporation of poorly soluble and low-volatile components depend on the ratio of their solubility in water and the equilibrium vapor pressure. One can see the relationship between the average values of the correlation coefficients Rxy and T, S\P and N (the number of humidity cycles, Table 3). Glycerol, which has unlimited solubility in water and virtually zero volatility at room temperature, probably falls out of this relationship. Both factors act in opposite directions, which creates uncertainty in the result.

Changes in atmospheric pressure, similar to changes in humidity, can accelerate the process of evaporation of volatile components. When the pressure decreases, the evaporation rate of all substances included in the composition of paper materials and writing compositions increases. It is logical to expect that the dynamics of the content of volatile components of writing materials will have a picture similar to changes in humidity.

The test results are given in Table 4.

Table 3: *Relationship between the dispersion indices of the chromatographic signal and the physicochemical properties of the solvent [8,13,14,15].*

	S - solubility in water, g/l	T boiling point, C	P- equilibrium vapor pressure at 20C (kPa)	S/P	Pearson's coefficient r_{xy}	Dispersion % σ
2-phenoxyetanol (PE)	26	244	5,2*	5,0	-0,52÷-0,84	45÷303
Glucerol (G)	unlimited	290	0,4 (at 50C)	∞	-0,14÷-0,39	29÷63
Ethylhexanol (EH)	0,7	185	7,33	≈0,1	-0,2 ÷+0,7	14÷64
benzyl alcohol (BA)	40	205	12,7	3,1	-0,08÷-0,7	18÷67

Table 4: *Results of studies of the dynamics of the content of volatile components due to pressure changes using the chromatograph mass spectrometry method.*

a в

Figure 1: *Micrographs of writing ink strokes before the process of artificial aging by pressure (a) and after the end of the aging process (b)*

The results presented in Tables 2 and 4 show a close analogy of the effects of humidity changes and pressure changes on the dynamics of the volatile components of writing materials. Frequent and deep changes in natural humidity and pressure accelerate the evaporation of volatile and soluble components of ink, introducing a large dispersion into chromatographic measurements.

IV. Conclusion

In world practice, there is a significant gap in understanding the fundamental processes of aging of props. It is meant that it is necessary to expand the list of factors influencing the dispersion of the results of determining the age of a stroke, namely, to fundamentally study humidity, atmospheric pressure, structure and composition of paper, as well as various processes occurring during aging [6].

Thus, currently the applied methods require revision and improvement in connection with new results.

Determination of the absolute and relative age of a document and its details is in great demand among courts and parties in the framework of pre-trial investigation, but it encounters the impossibility of ensuring the quality of examinations due to the imperfection of existing physical and chemical models of aging, ignoring natural climatic factors. These are not random phenomena, but a consequence arising from a misunderstanding that a document is the most important material evidence, especially in civil and arbitration proceedings.

Overcoming this problem will help to significantly improve the quality and validity of court decisions in all types of cases under consideration and reduce the risks of obtaining erroneous court decisions.

Abstract

It is known that the final result of risk analysis is the determination of the consequences of explosions and fires at a hazardous facility. One of the most important indicators used in performing a risk analysis is the probability of occurrence of an ignition source.
The presented work proposes a method for taking into account the probability of mixture ignition. It is indicated that such an assessment is more plausible and consistent with observations and does not contradict the need for personnel participation in localizing an emergency release.

Keywords: emergency release, risk, ignition source, probability, oil spill, gas-air mixture

Introduction

The final stage of risk analysis is to determine the consequences of explosions and fires at a hazardous production facility (HPF). The final result of a risk analysis can be obtained if there is a reliable base of initial data, reference (statistical) data, a meaningful physical model of the processes of explosions and fires, and a completed mathematical model of analysis.

The input data includes the following:

- List of blocks included in the HPF;
- Technological diagram of connecting blocks;
- Performance of installations consisting of analyzed blocks;
- Characteristics of the blocks, including their volume, operating pressure, degree of filling, name of the products filling the block;
- Distribution of personnel on the territory of the hazardous production facility (HPF).

Reference data includes:

- Physico-chemical properties of the products filling the blocks, including properties characterizing their explosion and fire hazard;
- Statistical data on partial and complete depressurization of blocks;
- Data on lightning activity in the area where hazardous production facilities are located (HPF).

One of the most important indicators used in performing a risk analysis is the "probability of occurrence of an ignition source" indicator.

Table 1, based on data from [1], presents the distribution of fires and explosions by ignition sources.

Distribution by ignition sources.

The share of explosions and fires initiated by lightning discharges is 9.7%.

To determine the probability of an ignition source, we use the methodology of Appendix 3 GOST 12.1.004–91 [2] for calculating the probability of a direct lightning strike on an object, taking into account other ignition sources.

For a stationary object, the probability of a direct impact is determined by the relationship

$$P_{is} = 1\text{-}e^{-N_{ls}\, t} \tag{1}$$

where, N_{ls} is the number of direct lightning strikes into an object in 1 year; t-duration of the observation period equal to 1 year.

Table 1: *The distribution of fires and explosions by ignition sources*

İgnition source	Total quantity, pcs.	%
Hot work:	10	32.3
Mechanical sparks	5	16,1
Fire technological installations;	3	9,7
Lightning strike;	3	9,7
Electric sparks;	4	12,5
External ignition sources;	2	6,5
Static electricity discharge;	1	3,2
Vehicle;	1	3,2
Careless handling of fire;	1	3,2
Other.	1	3,2
Total	**31**	**100**

For round objects

$$N_{ls} = (2R+6H)^2 \cdot n_{ls} \cdot 10^{-6} \tag{2}$$

Here R - is the radius of the cloud within the boundaries of the lower concentration flammable limit (LCFL) or the radius of the flammable liquid spill, m; H - is the height of the cloud, equal to R_{LCFL} for a hemisphere with a ground-based gas release, m; during a spill FL-N=0. n_{ls} is the average number of lightning strikes per 1 km^2 of the earth's surface [3, 4].

Let's perform a control calculation to determine the number of direct lightning strikes into an object occupying an area of territory that accounts for 1 lightning strike per year. This area is equal to f1=1000000/3=333000 m^2. Base radius R= $(333000/3.14)^{0.5}$=325.6 m. For control calculation we take H=R. Then N_{ls} = $(2\cdot325.6+6\cdot325.6)^2 \cdot 3\cdot10^{-6}$ =20.35 1/year. The number of strikes of a discharge into an object occupying an area with the number of lightning strikes equal to 1 per year turns out to be 20.35 times greater than the number of lightning strikes.

To determine the probability of lightning strikes from a cloud of gas-air mixture, it is necessary to adjust the N_{ls} dependence taking into account the lack of electrical conductivity of the gas-air mixture. To do this, we eliminate the height part by equating the H term of the equation to zero. Then the equation for an object that does not generate electricity is transformed to the form:

$$N_{ls} = (2R)^2 \cdot n_{ls} \cdot 10^{-6}$$

When studying the possibility of igniting a cloud of a gas-air mixture (GAM), we take R = R_{LCFL}, and when studying the possibility of a liquid spill, R = D/2, where D - is the diameter of its spill.

To check the obtained dependence, we perform a control calculation. Let's find the number of lightning strikes into a hot water cloud with a radius of the lower concentration limit of ignition (LCFL) equal to 325.6 m.

$$N_{ls} = (2\cdot325.6)^2 \cdot 3\cdot10^{-6} = 1.27 \text{ 1/year}$$

The non-convergence of the result reaches 27%. The source of calculation error is the incorrect representation of the object area in the form of a square of twice the radius of the

LCFL. A more accurate value of N_{Is} can be obtained after specifying the area of projection of the GAM cloud onto the Earth's surface in the form

$$N_{Is} = \pi \cdot R^2 \cdot n_{Is} \cdot 10^{-6}$$

Check: N_{Is}=3.14·325.6^2 ·3·10^{-6} =0.9992 1/year.

To take into account other ignition sources, we introduce an additional factor k=10 into the N_{Is} equations. Then it is converted to mean

$$N_{Is} = 10\pi \cdot R^2 \cdot n_{Is} \cdot 10^{-6}$$

After substituting the obtained value of N_{Is} into the original equation, we finally obtain a formula for calculating the probability of the appearance of an ignition source affecting a cloud of hot water or a spill of flammable liquid within the boundaries of the possible ignition of an object:

$$P_{is} = 1 - e^{-x}$$

where,

$$x = 10\pi \cdot R^2 \cdot n_{Is} \cdot \tau \cdot 10^{-6}, \quad (4)$$

Let's plot the dependence $P_{is} = f \cdot (R_{LCFL})$ at $x = 10\pi \cdot R^2_{LSFL} \cdot n_{Is} \cdot \tau \cdot 10^{-6}$.

Analysis of the graph presented in Figure 1 allows us to draw the following conclusions:

1. The larger the affected object (GAM clouds of hot water or a spill of hot liquid), the more realistic the completion of an emergency release by ignition of a flammable substance.
2. Small targets are characterized by a low probability of ignition of the emission.
3. The dependence of the probability of the appearance of an ignition source Reese on the size of the affected object allows us to establish the probability of distribution of the consequences of the release according to accident scenarios. The release may result in combustion or dispersion. Possibility of ignition or dispersion. The probability of ignition is equal to the probability of the appearance of an ignition source, that is, $P_{ignit} = R_{is}$. The probability of release dissipation is equal to the difference $P_{disp} = 1 - P_{is}$.

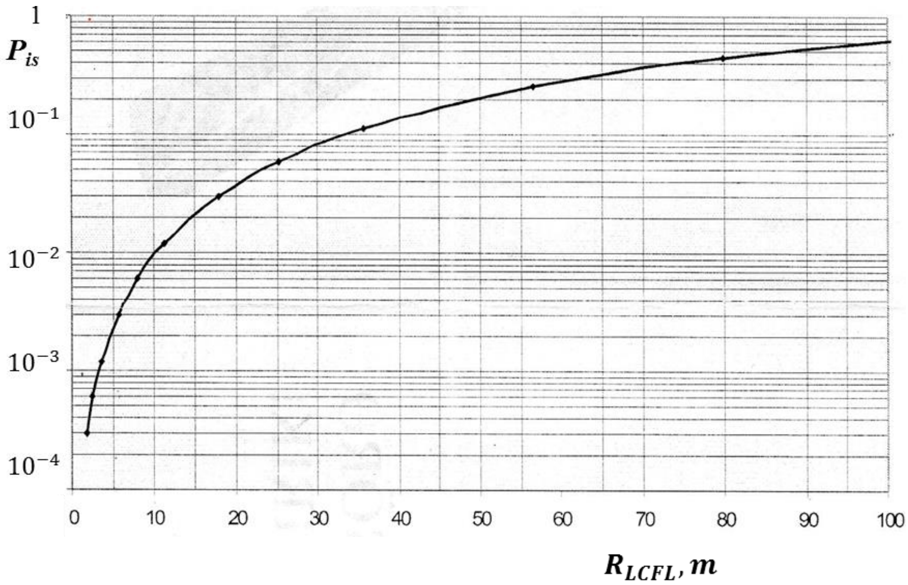

Figure 1: *Probability of the appearance of an ignition source*

4. The probability distribution of accident scenarios, adopted in GOST R 12.3.047–98, is incorrect in that this distribution does not depend on the size of the affected object.

Let us find the dependence of the frequency of implementation of the scenario with ignition of the emission on the size of the hot water cloud or the diameter of the gas liquid spill (GAM):

$$N_{ignit} = N_{depr} \cdot P_{is} \quad (5)$$

where

N_{ignit} is the ignition frequency of hazardous product emissions, 1/year;

N_{depr} - frequency of unit depressurization, 1/year;

R_{is} - is the probability of manifestation of the ignition source, fraction.

The release frequency in accordance with the database [5] is: with partial depressurization - $1 \cdot 10^{-4}$ 1/year, with complete depressurization - $1 \cdot 10^{-5}$ 1/year. When using the Methodology database [6], the specified values must be adjusted.

The probability of a fire scenario occurring depends on the size of the target. With partial depressurization, the emission volume is less than with complete depressurization. In accordance with this, the probability of ignition of the emission during partial depressurization is less than during complete depressurization. Let us assume that with partial depressurization the volume of gas in the release is 10 m^3, and with complete depressurization it is 1000 m^3.

Let us find R_{LCFL} for each case of depressurization.

For partial depressurization $R_{LCFL} = 1.633(10/5)^{0.333} = 2.06$ m. This value corresponds to the probability of the appearance of an ignition source

$$P_{is}=1-2.73^{-x}$$

where, $x=R^2_{LCFL} \cdot n_{Is} \cdot \tau \cdot 10^{-5}$. $x=3.14 \cdot 2.06^2 \cdot 3 \cdot 1 \cdot 10^{-6} = 4 \cdot 10^{-4}$. $R_{LCFL}=1-2.73^{-0.0004}=4 \cdot 10^{-4}$

In case of partial depressurization of a block with the release of 10 m^3 of gas, the probability of the scenario with the ignition of a hot water cloud being realized is (GAM) 0.0004.

If the block is completely depressurized, $R_{LCFL}=1.633(1000/5)^{0.333} = 9.53$ m.

For this case, $x = 3.14 \cdot 9.53^2 \cdot 1 \cdot 10^{-5} = 8.56 \cdot 10^{-3}$. The probability of the scenario with the ignition of a hot water cloud being realized will be (GAM)

$P_{disp} = 1-2.73^{-0.000856} = 8.59 \cdot 10^{-3}$. The probability of cloud dispersal without its ignition during partial depressurization will be $P_{disp} = 1-0.0004 = 0.9996$. If the unit is completely depressurized, the probability of the release dissipating without igniting the cloud will be $P_{disp} = 1-0.00856 = 0.991$.

Example:

Determine the parameters of an oil spill fire and explosion of a gas-air mixture cloud at an oil separation installation.

Initial data:

The installation refers to on-site structures where there is service staff. The oil production capacity of the installation is 1000 m^3/hour, the gas factor of reservoir oil is 70 m^3/m^3, the pressure at the beginning of degassing is 8.5 MPa. The possibility of depressurization of the pipeline located in the circuit before the separator (first calculation option), the oil pipeline after the separator (second calculation option) and the gas pipeline (third option) is being considered.

Solution:

Determination of the volumes of gas and oil in the release. This problem is solved by the volume of gas capable of activating DVK sensors installed at a distance of 11.2 m from the possible release site. $V_k = (0.01 \cdot 11.2/0.041)^3 \cdot V_k = 20.38$ m^3. The results of the determination are presented in Table 2.

With an average release duration of 1 hour, the share of oil and gas extraction does not exceed 0.06% of the nominal value. The release may go unnoticed until the next operator walks through the installation.

The radius of the explosion affected area, determined using the TNT equivalent method, is overestimated by 10 times. In this regard, the greatest danger is the release of oil. If we take into account the dynamics of the development of an accident associated with an oil release, then a catastrophic release should be considered impossible, since the oil slick will be detected by personnel when walking around the installation before the gas control system is activated. The scenario of an accident with massive flooding of the installation with oil should be classified as hypothetical. The likelihood of such an accident occurring is negligible.

Table 2: *The determination of the volumes of gas and oil in the release*

	First option		Second option		Third option	
	Gas	oil	Gas	oil	Gas	oil
Volume of gas in the cloud, m^3	20,38		20,38		20,38	
Residual gas factor, % vol.		70		35,16		
Volume of oil and release, m^3		0,29		0,58		0
R_{LCFL}, m	2,24		2,24		2,24	0
Spill diameter, m		3,03		4,3		
Release frequency, 1/year	$1{,}0 \cdot 10^{-4}$	$1{,}0 \cdot 10^{-4}$	$1{,}0 \cdot 10^{-4}$	$1{,}0 \cdot 10^{-4}$	$1{,}0 \cdot 10^{-4}$	
Probability of an ignition source	$5 \cdot 10^{-4}$	$1 \cdot 10^{-3}$	$5 \cdot 10^{-4}$	$1{,}8 \cdot 10^{-3}$	$5 \cdot 10^{-4}$	
Radius from the affected area on an outdoor installation, R_0, m	0	1,5	0	2,15	0	0
Frequency of explosions (fires), 1/year	$5 \cdot 10^{-8}$	$1 \cdot 10^{-7}$	$5 \cdot 10^{-8}$	$1{,}8 \cdot 10^{-7}$	$5 \cdot 10^{-8}$	0

Conclusions

1. The probability of the appearance of an ignition source depends on the size of the hot water cloud within (GAM) the boundaries of the LCFL or the size of the flammable liquid spill.

2. The probability of ignition of an emission, established in the Methodology [6] and GOST as a constant value independent of the size of the flammable object, does not correspond to probability theory and cannot be used in risk analysis calculations.

3. Calculation of the probability of the occurrence of an ignition source connects the risk research procedures into a continuous chain, allowing to achieve the result of the analysis.

Abstract

Density (ρ), and speed of sound (W) of natural mineral waters from the region of south Russia (North Caucasus, Essentuki wells ES№1, ES№2, ES№4, and ES№17) have been measured as a function of temperature. The measurements were made over the temperature range from (278 to 343) K at atmospheric pressure. Anton Paar DSA 5000 M sound-speed analyzer has been employed to the simultaneously measurements of the density and speed of sound of the mineral water samples. The combined expanded uncertainty of the density, speed of sound, atmospheric pressure (P_0), and temperature (T) measurements at the 95 % confidence level with a coverage factor of k = 2 is estimated to be ± 0.005 kg·m^{-3} (or 0.01 %), 0.1 %, and 15 mK, respectively. The measured temperature behavior of density, and speed of sound for natural mineral waters were compared with the values for pure water (IAPW formulation) and for various binary aqueous salt (NaCl, Na_2CO_3, Na_2SO_4, etc.) solutions. The measured values of density, and speed of sound were used to develop correlation models for the temperature and ion species concentration dependences (Riedel's characteristic constants of the ions determination). The measured properties as a function temperature at atmospheric pressure have been used as a reference data for prediction of the high-pressure thermodynamic behavior.

Keywords: mineral water, geochemistry, density, chemical composition

I. Introduction

Multicomponent aqueous salt solutions play a major role in both natural and industrial processes. Most of Earth surface is covered by water. Natural mineral water is a multicomponent aqueous solution containing varying amounts of dissolved solids and gases. According to the European Legislation (2009/54/EC Directive), physical and chemical characterization is used to make a classification of the different mineral waters [1]. The exploitation of thermal and mineral water resources requires availability of reliable thermodynamic and transport property data at high temperatures and high pressures. For example, these data are needed for estimate the likehood of scaling and corrosion developing within the wells and surface equipment, and to predict the commercial lifetime of the exploitation project. The temperature dependence of the density of geothermal and mineral waters has also to be considered when defining the dimensions of the pumping systems because buoyancy effect decreases pumping requirements. Use of pure water or geothermal brine models (synthetic brines like binary or ternary aqueous salt solutions) properties instead of their natural mineral water values, in practical application (engineering calculations), leads to inaccuracy and incorrect estimation of the practical calculations, for example, pumping requirements. This work is a part of our long-term continuing program of experimental study and modeling of the thermodynamic (*PVT*, heat capacity, vapor-pressure), acoustic (speed of sound) and transport (viscosity and thermal conductivity) properties of natural thermal and mineral waters at high-temperature and high-pressure [2-5]. In our recent publications [2-5] we have experimentally studied density, speed of sound, and viscosity of natural geothermal and mineral waters from various regions over the world (Azerbaijan, Turkey, and Germany) with different chemical compositions. The present results are considerably expanding the available data base on density of natural geothermal and mineral waters from various regions of the South Russia and around the world with various chemical compositions.

II. Methods

The chemical composition was obtained with the ionic chromatograph Dionex 100 + ICS 100. The pH, was determined at 293.15 K using the standard NF T 90-008.

The density and speed of sound of the natural mineral water samples at atmospheric pressure at elevated temperatures have been simultaneously measured with a sound-speed analyzer DSA 5000 M (Anton Paar Instrument, Austria). The method (experimental details, the physical basis and theory of the method, procedure of measurements, uncertainty assessment, etc.) and apparatus have been described in our several previous publications [2,4,5]. Only a brief review and essential information will be given here. The two-in-one instrument is equipped with a density and a sound velocity cell thus combining the proven Anton Paar oscillating U-tube method with a highly accurate measurement of sound velocity. Both cells are temperature-controlled by a built-in Peltier thermostat. The temperature, where located the U-tube, was controlled with a solid-state thermostat, working via Peltier effect with a precision of ±0.005 K. The temperature of the experimental cell was measured using the (ITS-90) PRT100 thermometer with an uncertainty of 0.03 K. The sample is introduced into the sound velocity-measuring cell that is bordered by an ultrasonic transmitter on the one side, by a receiver on the other side. The transmitter sends sound waves of a known period through the sample. The speed of sound can be calculated by determining of the period of received sound waves and by considering the distance between the transmitter and receiver. The digital density analyzer in these instruments uses a U-shaped vibrating tube (VTD). The working principle of an oscillation-type densimeter is based on the law of harmonic oscillation, in which a U-tube is completely filled with the sample under study and subjected to an electromagnetic force. Density measurements with a VTD are based on the dependence of the period of oscillation of a unilaterally fixed U-tube on its mass. Due to complexity of the geometry of the vibrating tube it requires very carefully calibration with a reference fluid of well-known density. The accuracy of the method is limited by the calibration procedure. The calibration of the VTD is very important step of the measurements and should be performed very carefully and frequently to keep the high accuracy using a few (minimum 2) references fluids (such as water, benzene, nitrogen, air, and toluene) whose *PVT* properties are well known. In the present study the calibration was performed using a few reference fluids such as air, double distilled, deionized and degassed water, benzene, and toluene with well-known *PVT* properties [6]. The reference data Lemmon et al. [6] were used to determine the temperature dependence of the calibration parameters in the working equation of the method [2,4,5]. Further information about the details of the experimental technique for density and speed of sound measurements has been provided in our previous works [2,4,5]. The density and speed of sound measuring ranges for DMA 5000 instrument are from (0 to 3000) $kg \cdot m^{-3}$ and from (1000 to 2000) $m \cdot s^{-1}$, respectively in the temperature range from (278.15 to 343.15) K. The uncertainties of the density and speed of sound measurements are 0.01 % and 0.10 %, with repeatability of 0.001 $kg \cdot m^{-3}$ and 0.10 $m \cdot s^{-1}$, respectively.

III. Results and Discussion

I. Chemical Composition

Thermal and mineral water samples was distributed directly from Essentuki springs. Chemical composition and pH of the mineral water samples taken from the EMW (ES№1, ES№2, ES№4, and ES№17) are presented in Table 1. The pH of the mineral water samples under study ranges from (6.2 to 7.5).

Table 1. Chemical composition (mg/L) of natural mineral waters from Essentuki wells

Due to pressure difference between underground and the near surface conditions (0.101 MPa), degassing (no stable components like dissolved gases such as CO_2, CH_4, H_2S, N_2, H_2 and O_2) occurs during production. Thus, in general, the mineral water samples are chlorine rich with Na and Ca, *i.e.*, the Na^+, Ca^{2+}, and Cl^- are dominant ions.

II. Density

Density measurements were performed at atmospheric pressure as a function of temperature from (278.15 to 343.15) K. The measured density data are presented in Table 2 and depicted in Figs. 1 to 3 in the $\rho-T$, $\rho-S$ (where S is the TDS concentration), and and $\rho-x_{NaCl}$ projections together with the values for pure water calculated from IAPWS fundamental equation of state (IAPWS, Wagner and Pruß) [7]. As can be noted from Fig. 1, the thermodynamic behavior of the mineral and thermal waters (also, for all aqueous salt solutions) governs by the properties of pure water (see Fig. 1), *i.e.*, the temperature dependence of the measured properties (density, and speed of sound) of mineral waters is determined through the pure water properties. Figure 1 also includes the values of density for the same mineral water samples measured using SVM 3000 visco-densimeter. As one can see from Fig. 1, the agreement between the both set of measurements is good enough, the average absolute deviations (AAD) are 0.008 % (ES№1), 0.014 % (ES№2), 0.009 % (ES№4), and 0.015% (ES№17). This confirms the accuracy and the reliability of the measured density data for the mineral water samples under study.

A major source of measuring uncertainties when using a density are the effect of bubbles of dissolved gases in the measuring cell. The bubbles can be formed during the filling procedure. However, the present instrument (DSA 5000 M) allows detect automatically the filling errors or bubbles forming in the sample during the cell heating.

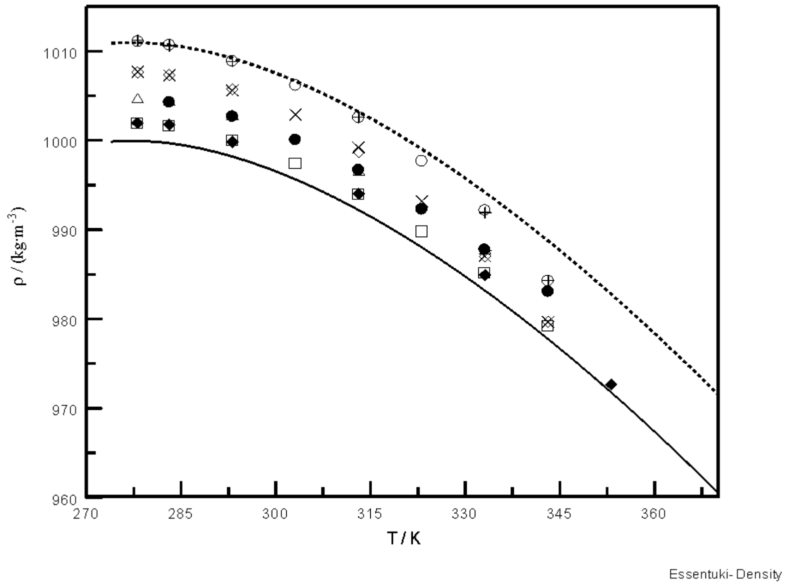

Figure 1: *Measured values of density of the mineral water samples using VTD (DSA 5000 M) together with the values measured with visco-densimeter (SVM 3000) and for pure water calculated from IAPWS formulation. Solid line is pure water values calculated from the IAPWS fundamental equation of state state (IAPWS, Wagner and Pruß, 2002). Dashed lines are calculated from the correlation model for the samples ES№17. From DSA 5000 M measurements: □ – ES№1; ● – ES№2; ✕ – ES№4; and ○ – ES№17. From SVM 3000 visco-densimeter measurements: ◆ – ES№1; △ – ES№2; ◇✕ – ES№4; and + – ES№17.*

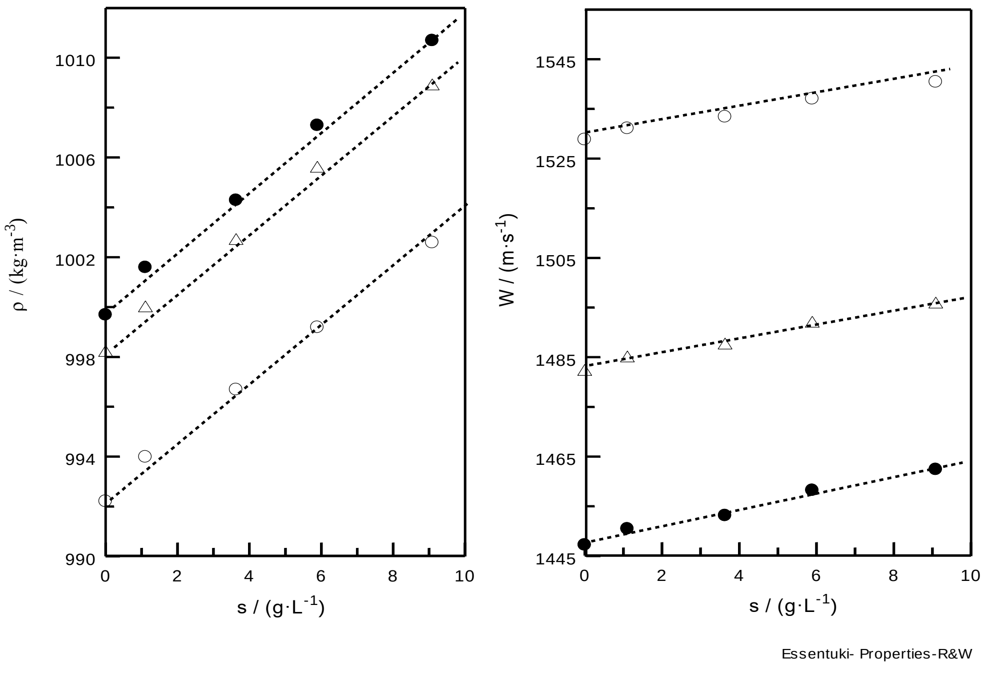

Figure 2: *Measured values of density and speed of sound for various mineral waters as a functions of mineralization (TDS, S) along the selected isotherms together with the values for pure water (S=0, IAPWS, Wagner and Pruß, 2002). Dashed lines are linear interpolations. ●-283.15 K; △-293.15 K; ○-313.15 K.*

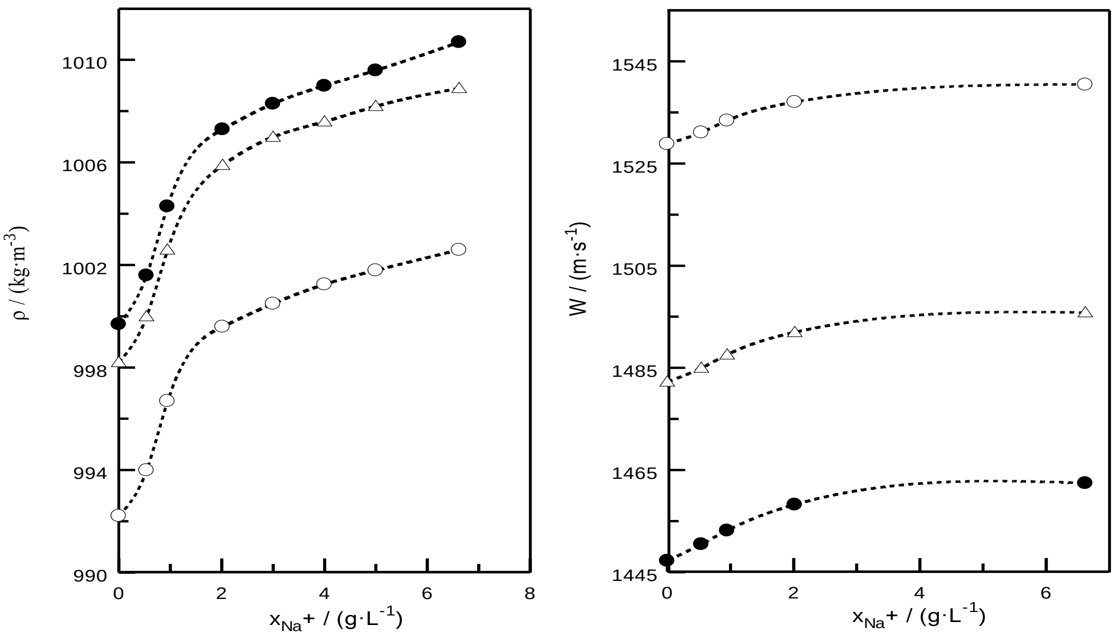

Figure 3: *Measured values of density (left) and speed of sound (right) for various mineral waters as a functions of Na^+ ion concentrations (sensitivity to Na^+ concentrations) along the selected isotherms together with the values for pure water (x_{Na+} =0, IAPWS, Wagner and Pruß, 2002). Dashed lines are interpolated values. ●-283.15 K; △-293.15 K; ○-313.15 K.*

Also, the measuring instrument (DSA 5000 M) allows to follow the sample filling process live on screen or recall stored images later. Therefore, the instrument allows verifying the correct sample filling and measurements later, *i.e.*, alert us of potential filling or bubble forming problems. At temperatures above 323 K, we found that heating of the samples (especially high concentrated samples ES№4 and ES№17) during the measurements causes the release of the dissolved gases. Therefore, the measured data at temperatures above 323 K are affected by dissolved gases. Above the 323 K the intensity of the gas release increases. At low temperatures (below 323 K) the effect of gas release to the measured properties can be neglected. The instrument automatically detects inhomogeneity and gas bubbles forming in the whole density measuring cell by an advanced analysis of its oscillation pattern and generates a warning message in real time for any single measurement, *i.e.*, the bubbles (gas release) in the sample are detected automatically during the experiment (instrument alert us of potential gas release problems). At temperatures below 323 K we did not observed any gas release problem in our experiment (no warning messages from the instrument were observed). To study of the effect of dissolved gases in the mineral water samples at high temperatures, the measurements at high pressures are required because the solubility of gases in liquids increases with pressure increasing.

Figure 2 shows the salinity (TDS) dependence of the density (left) along the fixed temperatures. As one can see, ρ–*S* dependence is almost linear function. In the limit, $S \to 0$, the measured density data becomes equal to the pure water values (IAPWS, Wagner and Pruß, 2002) at each fixed temperature. The present extrapolated to zero salinity $(S \to 0)$ density data and the values for pure water calculated from IAPWS formulation (Wagner and Pruß, 2002) are in good (discrepancy is AAD=0.003 %) agreement (see Fig. 4). This excellent agreement between the present extrapolated data and IAPWS (Wagner and Pruß, 2002) calculations for pure water confirms the reliability and high accuracy of the present measurements for the mineral water sample and correct operation of the measuring instrument and the procedure of measurements. The measured values of density for various mineral waters as a function of Na^+ ion concentrations (sensitivity of the measured densities to Na^+ concentrations) along the selected isotherms together with the values for pure water (*S*=0, IAPWS Wagner and Pruß,

2002) are depicted in Fig. 3 (left). As this figure shows, in the low concentration range ◎⤙⤙◎x_{Na^+} <2 g/*L*, rapid increase of the density along the isotherms is observing. At high concentration of Na^+, above >2 g/*L* gradually increases of the measured density with almost constant slopes is observing.

III. Speed of Sound

Measurements of the speed of sound for the same natural mineral water samples were performed at atmospheric pressure as a function of temperature in the same temperature range as in density experiment, namely, from (278.15 to 343.15) K. The measured speed of sound data is presented in Table 2 and depicted in Figs. 2,3 (right), 4, and 5 in the *W*◎⤙◎◎ *W*◎⤙⤙◎◎*W*◎◎*S*,, and *W*◎◎x_{Na^+} projections. As one can see from Figs. 4 and 5, the temperature and density behavior of the speed of sound, as a density and other properties, similar pure water behavior (Wagner and Pruß, 2002) . However, speed of sound, in contrast to density, is less sensitivity to the effect of gas releases. The measured speed of sound (Fig. 2 right) of the mineral water is almost linear function of the TDS concentration like density. The sensitivity of the speed of sound data to concentration of the sodium ions (main component of the mineral waters) shown in Fig. 3 (right). As one can see, a speed of sound is smoothly increasing with x_{Na^+}. The present measured speed of sound data for mineral water samples deviates from those for pure water (IAPWS standard data, Wagner and Pruß, 2002) within (0.13 to 0.27) % for ES№1, from (0.28 to 0.42) % for ES№2, from (0.53 to 0.83) % for ES №4, and from (0.75 to 1.13) % for ES№17. At high temperatures the deviations are lower than at low temperatures.

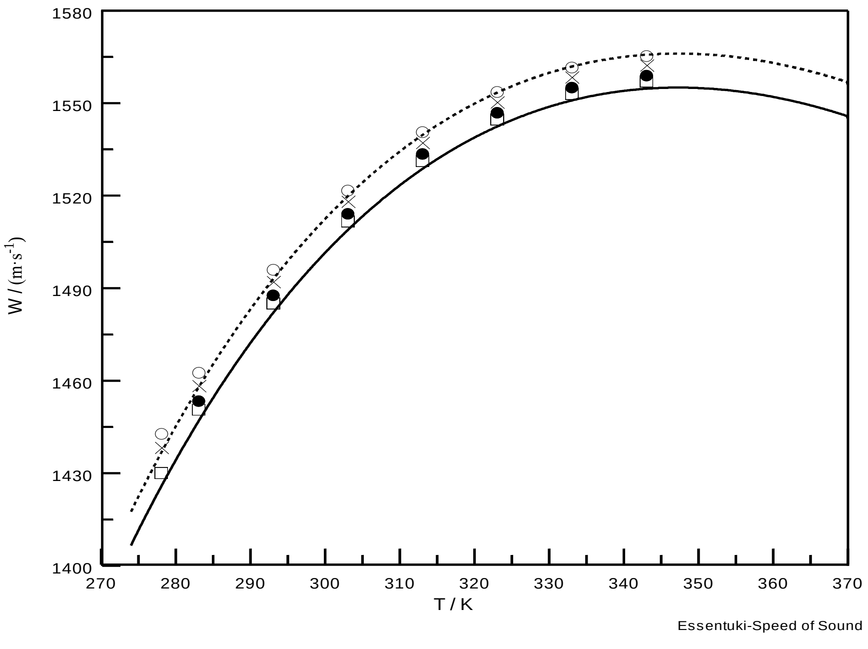

Figure 4: *Measured speed of sound for various mineral waters as a function of temperature together with the values for pure water calculated from IAPWS formulation. Solid line is pure water values calculated from the IAPWS fundamental equation of state (Wagner and Pruß, 2002) . Dashed lines are values calculated from the predictive correlation model for the sample ES№17. The symbols are the same as in Fig. 1.*

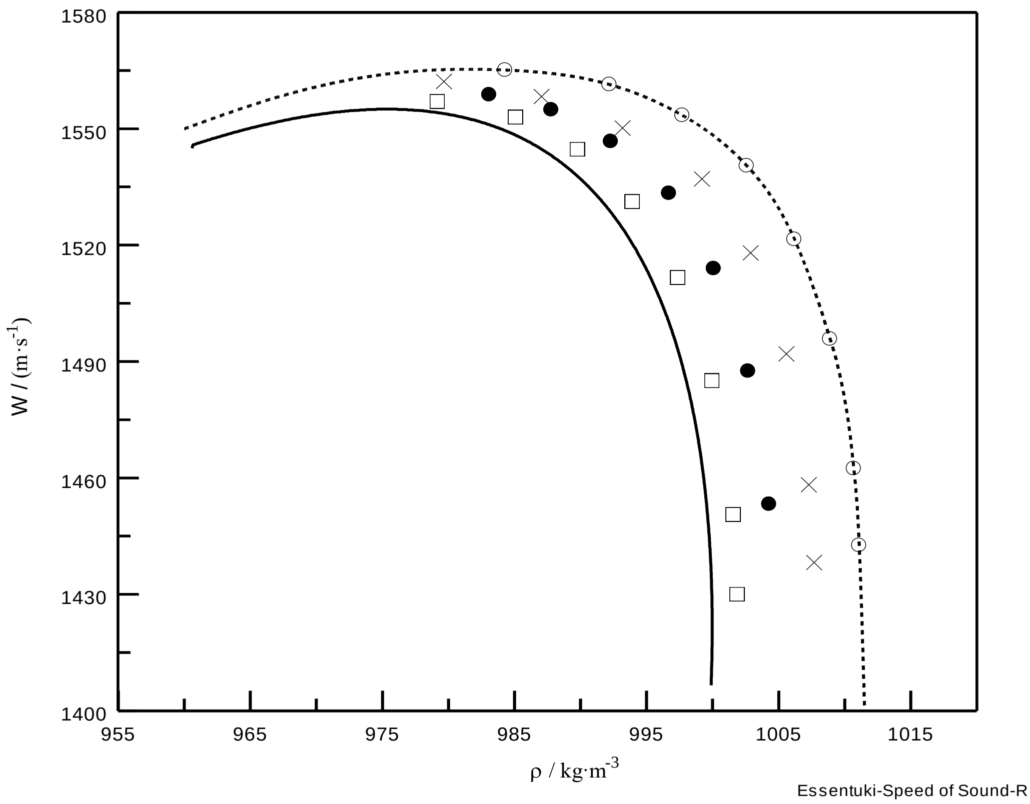

Figure 5: *Measured speed of sound for various mineral waters as a function of density together with the values for pure water calculated from IAPWS formulation. Solid line is pure water values calculated from the IAPWS correlation (Wagner and Pruß, 2002). Dashed line is calculated from the prediction model. The symbols are the same as in Fig. 1.*

IV. Correlation Models for Density, and Speed of Sound

Since there is no theory available for the thermodynamic (equation of state) and transport properties (temperature and concentration dependence correlation models) of multicomponent aqueous solutions, its evaluation is empirical and based solely on experimentally obtained data. Therefore, the present measured density data as a function of temperature were represented by polynomial type temperature function

$$\rho(T) = a_0 + a_1 T + a_2 T^2 . \tag{1}$$

The derived optimal values of fitting parameters are given in Table 3. As one can see from Table 1, the AAD between measured and calculated from Eq. (1) values of density for samples ES№1, ES№2, ES №4, and ES №17 are 0.009, 0.020, 0.015, and 0.017 %, respectively.

Measured speed of sound data was fitted to the same quadratic function of temperature

$$W(T) = b_0 + b_1 T + b_2 T^2 . \tag{2}$$

The values of derived adjustable coefficients of Eq. (2) are presented in Table 5 together with deviation statistics. As can be seen, AAD between the measured and calculated values of speed of sound data for ES№1, ES№2, ES №4, and ES №17 is 0.062, 0.052, 0.061, and 0.058 %, respectively.

Table 3: *Values of fitting parameters (a_i) of the correlation Eqs. (1), for the density of mineral water samples together with the deviation statistics*

ES№4	-2040.7540	21.1368	-0.03101	0.06	0.00	0.07	0.02	0.09
ES№17	-2008.0588	20.9698	-0.03077	0.06	-0.00	0.07	0.02	0.08

V. Concentration dependence of the density, and speed of sound

As was mentioned above, thermodynamic properties of all aqueous salt solutions, thermal and mineral waters can be represented based on pure water properties (IAPWS formulations, Wagner and Pruß, 2002), because pure water is the dominant constituent and governs aqueous systems properties, see above Figs. 3, 6, and 8. The present experimental density, and speed of sound data for the mineral waters were fitted to the Riedel's correlation equations [8].

$$\rho(T, x_i) = \rho_{H_20}(T)\left(1 + \sum_{i=1}^{n} a_i x_i\right), \tag{3}$$

$$W(T, x_i) = W_{H_20}(T)\left(1 + \sum_{i=1}^{n} b_i x_i\right), \tag{4}$$

where $\rho_{H_20}(T)$, and $W_{H_20}(T)$ are the density, speed of sound (IAPWS formulation, Wagner and Pruß, 2002) of pure water respectively at a temperature of T and at atmospheric pressure; x_i is the concentration of ions (g/*l*); n is the number of main components of the mineral water ; a_i , b_i are the density, and speed of sound fitting coefficients (Riedel's characteristic constants of the ions) for each ion species *i*, which are defining the contribution of each single ion species to total measured properties. For the present mineral water samples, we have selected 8 main components (ions): Na^+, Ca^{+2}, Mg^{+2}, K^+, S^+, Si^+, SO_4^{-2}, and Cl^{-1} which contributions to the measured properties of the mineral waters are significant. The effect of other ions to the measured properties is negligible small. As can be note, from Eq. (3), (4) the temperature dependence of the $\rho(T, x_i)$, and $W(T, x_i)$ of mineral waters is determined through the temperature behavior of pure water properties, $\rho_{H_20}(T)$, and $W_{H_20}(T)$, see Figs. 1, and 4. All measured $\rho(T, x_i)$, and $W(T, x_i)$ data for various temperatures and concentrations (ES№1, ES№2, ES№4, and ES№17) together were fitted to Eqs. (3) and (4). The derived values of the Riedel's characteristic constants (a_i , b_i) for 8 selected ions of Na^+, Ca^{+2}, Mg^{+2}, K^+, S^+, Si^+, SO_4^{-2}, and Cl^{-1} are presented in Table 4.

Table 4: *Characteristic constant (Riedel's characteristic constant of the ions) a_i, b_i, and c_i for density, and speed of sound correlation models Eqs. (3)and (4) for basic ions in the mineral water samples*

Ions	a_i (density) (l/g)	b_i (speed of sound) (l/g)
Ca^{+2}	-0.1345	-0.1345
K^{+}	-0.0945	-0.0945
Mg^{+2}	-0.1435	-0.1435
Na^{+}	-0.0545	-0.0545
S^{+}	0.1555	0.1555
Si^{+}	-0.1245	-0.1245
Cl^{-1}	0.3555	0.3555
SO_4^{-2}	0.0555	0.0555

As one can see, the values of the Riedel's characteristic constants (a_i , b_i , c_i) for density and speed of sound are the same. This means that the contribution of the same ion specie to the density and speed of sound is the same. Also, the Riedel's characteristic constants for all cations are negative (except for S^+), while for anions are positive. Thus, using the present measured density, and speed of sound data for the mineral water samples we can separate the contribution of different ion species to the total measured properties. and natural geothermal waters.

As can be note from Eqs. (3) and (4), the Riedel's model is the linear function of the concentration of ions. However, to improve the accuracy of the experimental data representations of the Riedel's model, the next terms ($x_i^{0.5}$, $x_i^{1.5}$, x_i^{2}) in expansion (Eqs. 3 and 4) should be used. More experimental thermophysical property data of thermal and mineral waters from various regions over the world with various compositions are needed to improve the accuracy of prediction of the models for any natural waters over the wide range of temperature and compositions of salt ions.

IV. Conclusions

The density, and speed of sound of four natural mineral water samples from the region of south Russia (CMW filed, ES№1, ES№2, ES №4, and ES №17) have been measured over a temperature range from (278 to 345) K at atmospheric pressure. Qualitative the measured temperature dependence of the density, and speed of sound of mineral water samples is similar to pure water behavior. Quantitatively the average differences between the measured mineral waters density, and speed of sound and pure water values (IAPWS standards) are within (0.2 to 1.1) %, and (0.15 to 1.13) %, respectively, which are much higher than their experimental uncertainties. At temperatures above 323 K, we found that heating of the samples (especially high concentrated samples ES №4 and ES №17) during the measurements, causes the release of the dissolved gases, which effects on temperature behavior of the density and speed of sound. We have demonstrated that the measured (ρ,W) data at atmospheric pressure can be used to predict high-pressure and high-temperature behavior of density ($P\rho T$) and speed of sound (WPT). If the thermophysical properties of mineral water are known at reference pressure (for example, P_0 =0.101 MPa) and any temperature, then their properties at high pressures at which this properties of pure water are known (IAPWS standards) maybe calculated by multiplying the properties of the mineral water at reference state, P_0 , and given temperature, T, by the ratio of the this property of pure water at the desired pressure to that at a known reference pressure, P_0 =0.101 MPa. Riedel's characteristic constants of the 8 selected ions of Na^+, Ca^{+2}, Mg^{+2}, K^+, S^+, Si^+, SO_4^{-2}, and Cl^{-1} for density, and speed of sound were estimated from the present measurements. We found that the values of Riedel's characteristic constants of the ion species for the thermodynamic properties (density and speed of sound) are the same. This means that the contribution of the same ion specie to the total measured density and speed of sound is the same. Also, the Riedel's characteristic constants for the all cations are negative (except for S^+), while for anions are positive.

Abstract

Digital transformation is a comprehensive approach. The processes of transforming the enterprise functioning through the business procedures digitization and the automation of implementation and management of specialized software for internal and external interactions as part of the country's digital ecosystem form the basis of the approach. In this regard, as well as in the conditions of ensuring import substitution against sanctions policy, the most pressing issue is the development of domestic software for managing the domestic enterprises at various levels and agro-industrial spheres (AIC). It is the production process of agricultural enterprises, to a greater extent than enterprises of other industries, that is influenced by various risks caused by climatic, technological, biological, etc. factors. The article examines the provision of automation of transport and warehouse operations when managing logistics processes at an agricultural enterprise through the development of special software. A block diagram of the control process automation is presented, taking into account the level hierarchy, the architecture of the process control automation system, individual elements of the developed software product (the algorithm of the program for controlling an automatic pallet stacker, the visualization system: the push-button screen for information support and the main screen of the operator's touch panel). A mathematical model for a program to lay non-standard workpieces (packages) on a pallet with the optimization of their placement has been generated. The calculation of the project implementation economic efficiency is suggested. The payback period is five months, provided the operator has got the necessary competence level. The article concludes that a similar management system can be implemented at various enterprises with warehouse space (industrial, agricultural, service industries, cargo transportation, etc.) in order to reduce risks (related to technological, man-made and human factors) during loading and unloading of packaged raw materials and products, and considered as innovative resource-saving technology as well as the part of import substitution and adaptation of software when managing logistics processes in the context of digital transformation.

Keywords: management system, decision making, digitalization, production, agricultural enterprises, transformation, transport and warehouse equipment

I. Introduction

Currently, much attention is paid to improving management processes at enterprises. This is due to the widespread introduction of methods and means that allow the decision maker (DM) to optimize the management procedure. Digitalization of the economy favourably contributes to this process, and the unstable geopolitical situation boosts the development of domestic software for implementation at all levels of organization and industrial management of enterprises. Let`s take for example the industrial sector, where the production of bulk materials such as cement, soda, and lime occupies one of the leading roles now. As for the agro-industrial complex, a lot of manufacturing and food processing enterprises make a significant contribution to ensure the economic security of the country. At the present stage of development, they all need digital technological innovations [1]. The installation of automatic systems related to the transportation and storage of goods [2], the mobile microprocessor systems for automating transport and warehouse operations [3], etc., which increase management efficiency and, ultimately, production volume while reducing costs (thereby contributing to an increase in income), is currently a relevant issue, especially in the context of economic processes digitalization. Similar operations are carried out in agricultural enterprises during transport and warehouse operations in grain production, dairy farming, etc. Moreover, when loading and unloading packaged raw materials or finished products, various risks arise (including those depending on the human factor), including a violation of the container when falling, injury to workers, failure of the packaging composition by date of production, etc. In this case, automation of process control will reduce the likelihood of a risky situation, including technological or man-made ones (for example, when transporting fertilizers or pesticides), thereby eliminating an increase in costs. In addition, the seasonality of agricultural production, the influence of weather and climatic factors affect the uneven workload of employees throughout the year, therefore, automation of a number of processes reduces the cost of additional hiring during certain time periods.

The object of the research is the automated process control system with a pallet stacker in the context of optimizing the organization of transport and warehouse operations when managing logistics processes at the agricultural enterprise. For clarity, we will consider this equipment using the example of stacking single packages on a pallet (for other types of packages it is the same). Until recently, these operations were performed manually, the productivity of such work was about 50 packages per hour. Modern equipment allows for stacking at a speed of up to 3000 packages [4]. The choice of the research issue is substantiated by the importance to consider the problem of introducing automatic palletizers from the viewpoint of package placement optimization, as well as in the context of reducing risks and introducing energy and human resource-saving processes.

II. Methods

Methods of the systems approach, logical analysis and synthesis, optimization modeling and algorithmization were used while researching the issue.

There are robotic palletizers and palletizers of a continuous type on the market. The former are used for the workpieces of different volumes and shapes. Mechanical arms, suction cups and other tools allow you to grab and place any objects. At the same time, robotic palletizers have limited productivity, while palletizers of a continuous type allow stacking from 600 to 3000 packages per hour. The former are more flexible and at the same time quite compact, while the latter are massive, but at the same time have greater productivity. Palletizing robots are mainly used in pharmaceuticals and logistics. At enterprises producing products in bottles, bags and bags, belt (continuous type) palletizers are used [5, 6]. They have a wide range of designs and are used in various fields of production: textile, food or industrial.

Overview of palletizers

I. Manual palletizers are practically no longer used due to low productivity and the risk of human error.

II. A large number of Russian enterprises are equipped with the latest automatic equipment. However, Industria 4.0 has not yet reached everyone. As for the pallet stacker, there are still quite a few enterprises that use semi-automatic installations [7]. Such palletizers are less productive. In addition, there is a need to employ people as duty personnel (at least 4 people, since the installation operates around the clock). And these are additional wage costs. Operator`s work is monotonous, which increases the risk of human error. Semi-automatic pallet stackers are not always equipped with a monitoring and control system: an operator touch panel, a program for a specialist's automated workstation (AWS), a SCADA system.

III. Digitalization has affected almost all areas of human life including industry. The main advantage of the industrial enterprises` digital transformation is the increase in productivity as the product development, production, packaging and logistics take much less time, and production costs are reduced [8, 9].

The operation of equipment using sensors without human intervention according to a specially written algorithm means stability and safety. In addition, the introduction of digital technologies allows you to interact with machines using visualization systems and automated workplaces.

Analyzing various enterprises, we can safely say that the use of semi-automatic equipment in modern production is economically unprofitable [10]. If we consider new enterprises or those where complete re-equipment is planned, then for them it is most advisable to use automatic pallet stackers. However, at the moment, enterprises in which a semi-automatic unit operates dominate [11]. Buying a new one is a very expensive decision, and the payback period is not quick. In this regard, the question arises of digital transformation of the technological process through full automation of the palletizer using modern high-quality equipment with the ability to work around the clock without human intervention. Therefore, the purpose of this work is to develop a control system for a semi-automatic pallet stacker when it is converted into an automatic one.

III. Results

Automation system development

We have developed a block diagram for automating the process of managing transport and warehouse operations at enterprises using a pallet stacker. Figure 1 shows the hierarchy of its levels with the corresponding components. The scheme fully corresponds to the sequence of logistics process management stages implementation. The decision maker is equipped with an operator's workstation and an HMI panel (upper level), used as a graphical process control panel. Thanks to this electronic installation, which facilitates the visualization of information received from devices, the performance of the technological control object is analyzed (lower level) and further work is adjusted taking into account the controller data (middle level). Operational remote control, using support for selected protocols, allows you to implement the interaction of peripheral equipment at the field level and optimize the control procedure to select relevant management actions.

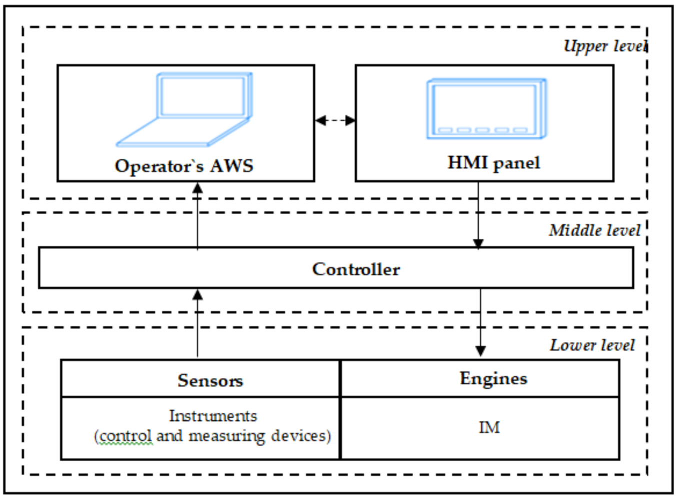

Figure 1: *Block diagram of automation of the management process*

Based on the block diagram, the architecture of the process control automation system was built (Figure 2).

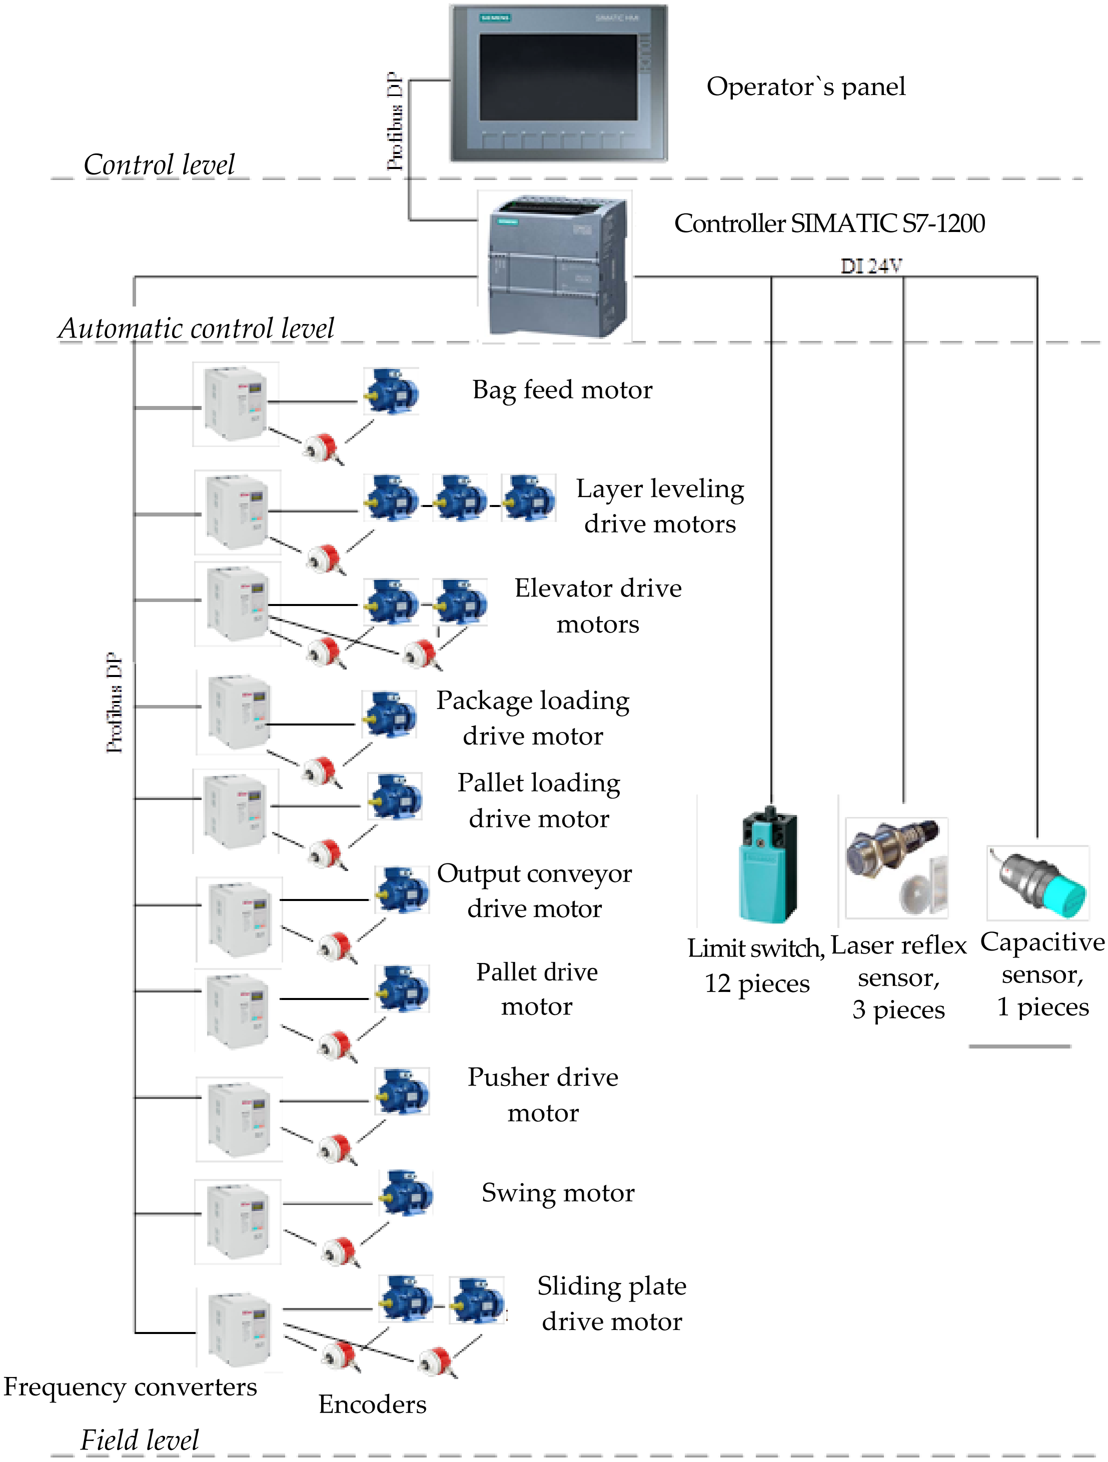

Figure 2: *Architecture of a process control automation system*

The field level consists of two limit switches, one capacitive and three laser reflex sensors. Also, in addition to sensors, the field level includes 14 asynchronous motors and 10 frequency converters, each controlling the speed of the drives of individual actuators. An encoder is connected to each frequency converter to provide speed feedback.

The field level is followed by the automatic control level, which consists of a programmable logic controller (PLC). All frequency converters are connected to the PLC via the ProfibusDP protocol. Limit switches and sensors are connected directly to the PLC.

The automated operator workstation consists of an HMI panel, which is also connected to the PLC via the ProfibusDP interface.

All drives as well as the control panel are connected to a programmable logic controller (Figure 3).

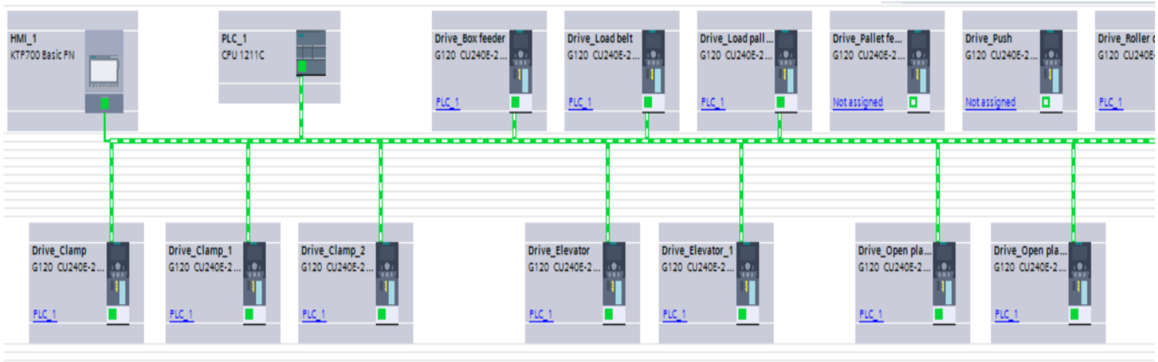

Figure 3: *Link with the controller*

All elements of the automation system architecture form a single automated system and provide a solution to all assigned automation tasks at this level.

Figures 4 and 5 show screenshots of the written pallet stacker control program.

Figure 4: *Reading signals from sensors*

Development of an adaptive system for searching the optimal location of non-standard workpieces.

The pallet stacker control program includes a special function for optimal placement of workpieces on a layer. This approach allows to place on pallets not only identical packages with strictly defined dimensions, but also completely different ones in shape and size. Such an adaptive system is especially important in the logistics of large enterprises that produce related products with different package dimensions on adjacent conveyor lines.

To perform this task, the following variables have been added to the program: L – length of the workpiece; S – is the area of the next layer; N – number of blanks. It is necessary to obtain m different types of workpieces with either length L_i or area S_i, where i is the type of workpiece ($i = 1, 2, ..., m$). The number of workpieces of the i-th type in the layer is known, i.e. the number of blanks that is necessary to form one layer – b_i. The total number of blanks produced by the enterprise is denoted by k. The arrangement of workpieces on a layer can be done in n ways. Then a_{ij} is the number of workpieces of the i-type, obtained by the j-method ($j = 1, 2, \dots, n$). The unused area in the j-method is C_j. It is necessary to arrange the workpieces in such a way that C_j (the total area of the gaps between the workpieces) is minimal. Let us denote by x_j the number of units of blanks cut by the *j* method. Find x_j>0 that satisfy the following restrictions.

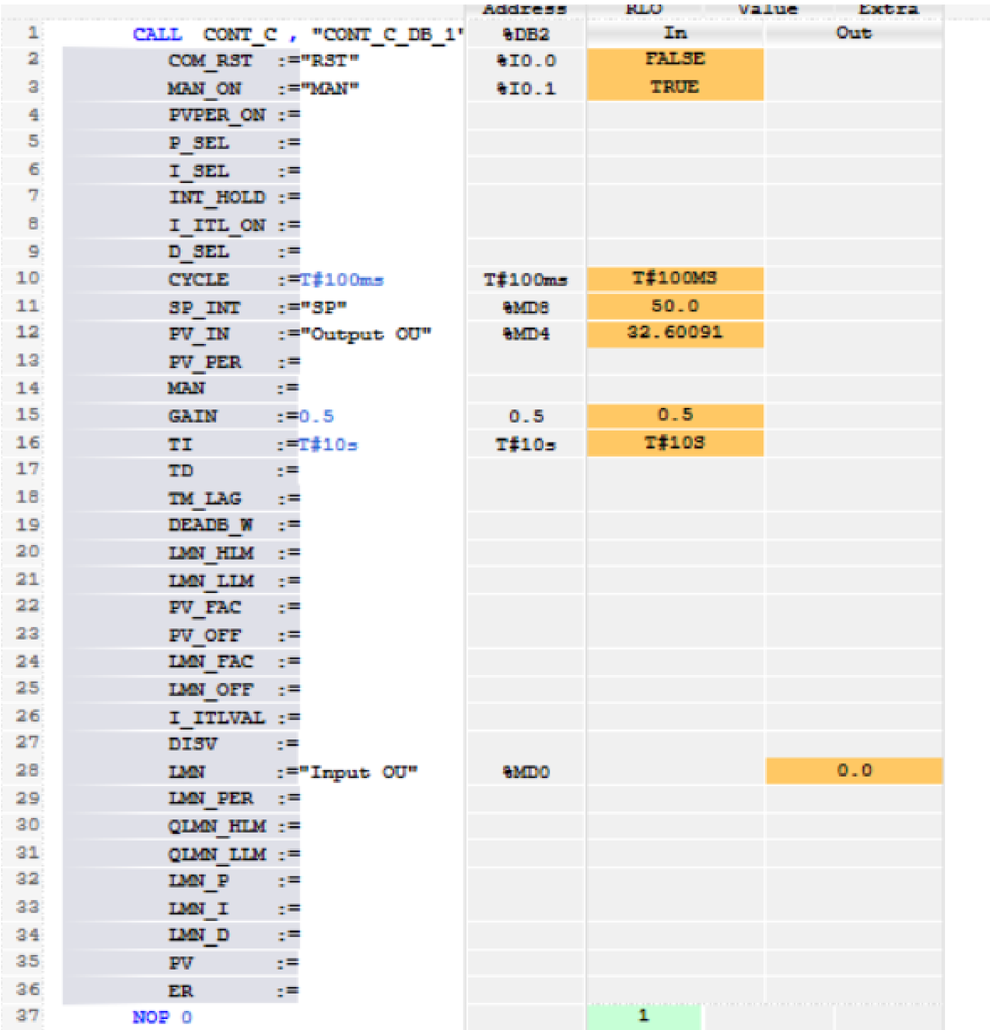

Figure 5: *Calling and setting up the control loop regulator*

Restriction on the number of blanks:

$$\sum_{j=1}^{n} x_j \leq N. \quad (1)$$

Production plan limitation:

$$\sum_{j=1}^{n} a_{ij} \cdot x_j = b_i, \quad (i = 1, \ldots, m). \quad (2)$$

This is exactly how many blanks of the *i*-type are obtained for all cut options. Based on the completeness condition, we obtain the following restrictions on the production plan:

$$\sum_{j=1}^{n} a_{ij} \cdot x_j = d_i \cdot k, \quad (i = 1, \ldots, m). \quad (3)$$

The total area of the gaps between the workpieces should be minimal, then the goal function will take the form:

$$\sum_{j=1}^{n} C_j \cdot x_j \to \min. \quad (4)$$

The value of the variables responsible for the number of blanks must be integer. To prevent the numbers with fractional parts, the program contains a solution to the linear integer programming problem, based on the following: it is necessary to calculate a value $X = (x_1, x_2, ..., x_n)$, for which the linear function:

$$Z = \sum_{j=1}^{n} c_j \cdot x_j \tag{5}$$

takes the maximum or minimum value subject to restrictions:

$$\sum_{j=1}^{n} a_{ij} \cdot x_j = b_i \quad (i = 1, ..., m); \tag{6}$$

$$x_j > 0, \quad (j = 1, \dots, n); \tag{7}$$

$$x_j \; - \text{ целые числа.} \tag{8}$$

Thus, the program calculates an option in which the maximum number of required blanks will be placed on the pallet with minimal gaps between each other.

IV. Discussion

Software development

The software under consideration is recommended to be installed on an automated workstation.

When launching the application, the following button form opens (Figure 6).

Figure 6: *Switch board "Information support for automated process control system of pallet stacker"*

This form contains a specific list of possible application working modes:

– requests for access to operational information;
– receiving a report – shift log;
– information about the developer.

The option to exit the application is provided.

Automation program development

To control an automatic pallet stacker, a program [12] is written in the visualized LAD language. The program assumes fully automatic operation without human intervention.

The operating algorithm is presented in Figure 7.

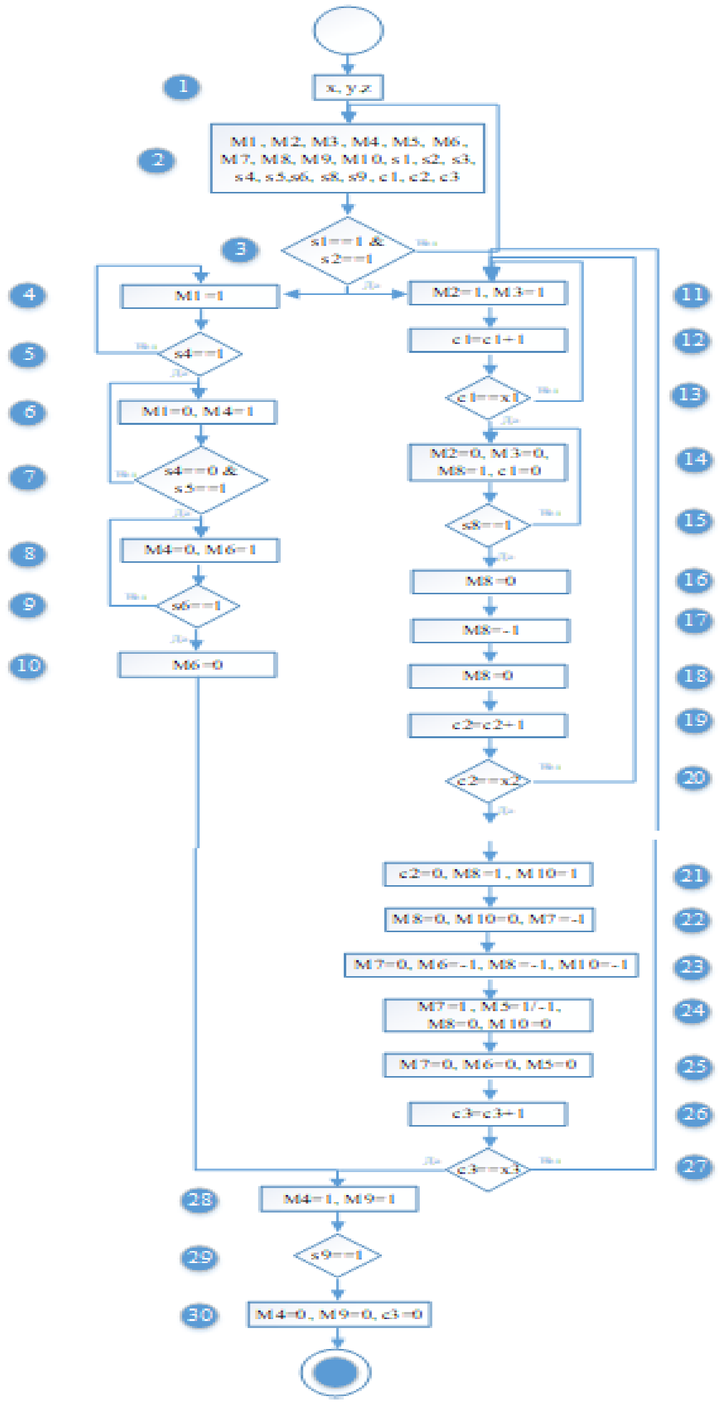

Figure 7: *Algorithm of the program for controlling an automatic pallet stacker*

The letter M denotes the corresponding drive, c – counter, s – sensor.

The program code provides for the main non-standard situations for displaying notifications and errors on the operator panel, which allows to quickly identify and eliminate the malfunction.

Visualization system development

A touch panel has been developed to visualize and control the technological process. It contains two screens. The first (Figure 8) is the main one, displaying the entire technological process; it is created directly for the operator's interaction with the automated system. The second screen displays diagnostic data.

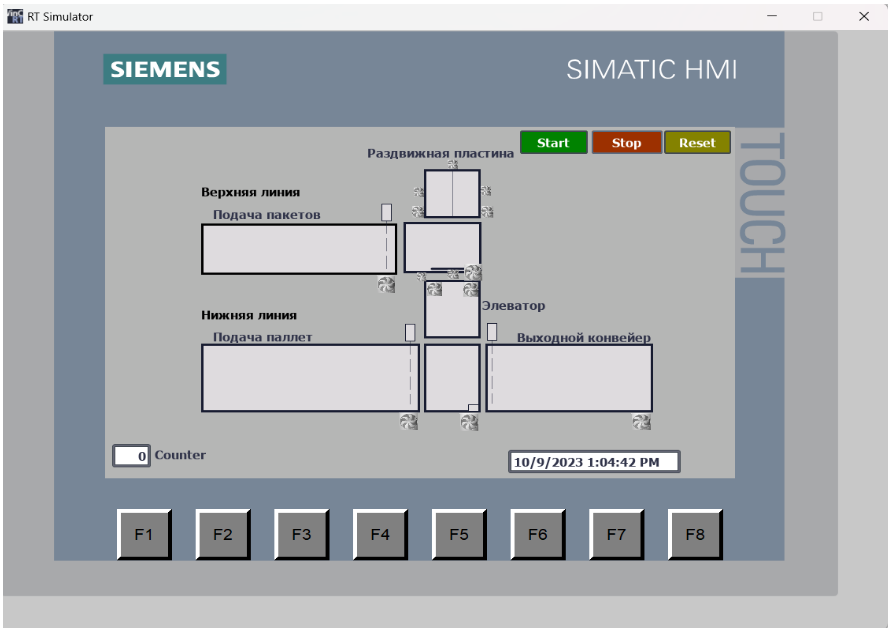

Figure 8: *Operator touch panel main screen*

The main screen contains three buttons for controlling the automatic palletizer: Start, Stop and Reset. These commands are duplicated with commands from the control cabinet. The F2 button scrolls to the second screen to view events that have occurred with the controller.

The tableau in the lower left corner displays the counted number of packages that have passed past the sensor installed on the conveyor feeding the packages.

The date and time are displayed at the bottom right.

The implementation of any innovation is known to require material and time costs. In addition, the level of competence of the specialist, who work on the new equipment, must meet the system requirements, otherwise, additional training costs will be required.

We have calculated the effectiveness of project implementation and the approximate payback period at one of the enterprises in AIC Orenburg region. Capital costs at the moment (capital costs mean the purchase of the necessary equipment for digitalization of the technological process and its installation) amount to 543,360 rubles, while profit from product sales will increase by 1,234,960 rubles.

The payback period of the project for the implementation of the developed control system for an automatic pallet stacker is calculated using the formula:

$$PP = \frac{I_0}{P}, \tag{9}$$

where PP is the payback period, months;

I_0 – initial investment, rub.;

P – net annual cash flow from product sales, rub.;

$$PP = \frac{543\ 360}{1\ 234\ 960} \approx 5 \text{ month.} \tag{10}$$

The payback period is quite short. The implementation of this project will significantly increase the enterprise competitiveness.

The presented project includes the purchase of new equipment and its installation. The experimental implementation of the developed product has proved that the supplementary operator training won`t be required.

The program for controlling the automatic pallet stacker can be used to organize the management of logistics processes within the framework of automation of transport and warehouse operations in the context of digital transformation at enterprises (with warehouse space) in a wide range of industries: in industry, in agriculture, in service sector, in the area of cargo transportation etc.

The developed control panel and software for the workstation displays the entire technological process and has all the necessary functions.

According to calculations, production volume will increase by 1.06%, and the profit from product sales will increase by 1.235 million rubles. The payback period of the project is about 5 months.

The developed automated system can be implemented both at a newly built enterprise and at the old one to replace outdated equipment. It is possible to modernize semi-automatic palletizers in order to fully automate them at the lowest cost.

This development contributes to the management processes digital transformation at the agricultural enterprise, which ultimately, together with the automation of technological processes and reducing risks (production, human, technological, etc.), will lead to increased production efficiency as a whole.

SOME ASPECTS OF APPLICATION OF INNOVATIVE TECHNOLOGY TO INCREASE OIL RECOVERY

Karim Seyidrza, Rashida Karimova
•
Azerbaijan State Oil and Industry University
karimov.zizik2013@yandex.com
rasida.aktau@mail.ru

Abstract

In the article, the study of the factors affecting the reduction of the oil yield of the oil fields located in the dry areas of Azerbaijan and in the final stage of development and the presence of large amounts of residual oil reserves in those fields are explained. At the same time, the problems of solving probes based on the application of modern innovative technologies and "smart" reagents for increasing oil production from those fields were explained with scientific and practical approaches.

Keywords: field, formation, development, oil recovery, flow rate, reagent, innovative technology

I. Introduction

Many fields of the Republic of Azerbaijan, exploited both onshore and offshore, have entered the final stage of development. The fields at the final stage are characterized by low oil flow rates - 0.8 t/day, high water cut - 85...98%, low reservoir pressure and temperature, formation of sand plugs in wells, high efficiency of "surface tension" of oil flow from the formation to the bottom of the well. Surfactants that affect the flushing and extraction of residual "dead oil" in fields are ineffective, and the high viscosity of reservoir oils has created difficulties in the application of progressive methods.

Despite the fact that 150-160 years have passed since oil was extracted from the onshore fields of Azerbaijan, the oil reserves that can be extracted from hydrocarbon fields that are still at the final stage of development are quite large. According to the latest estimate by specialists from the company De Golyer and MacNaughton, the potential of oil reserves on the Absheron Peninsula is 2 billion barrels (Fig. 1).

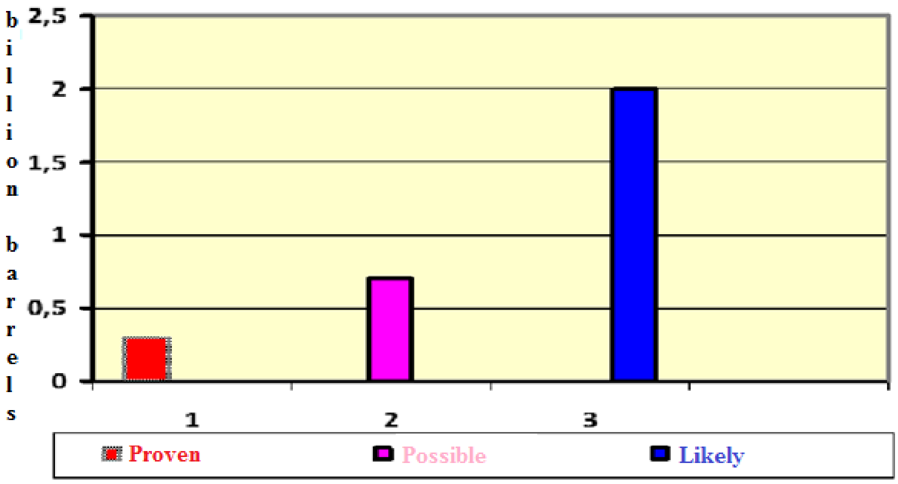

Figure 1: *Proven, possible and probable total onshore oil reserves*

Extracting oil from old fields is a complex production process involving many complex steps. To extract residual "dead oil", and their high prices have created difficulties in the application of advanced extraction methods [1].

Azerbaijan does not produce enough surfactants to extract residual “dead oil”, and their high prices have created difficulties in the application of advanced extraction methods/

In addition, in fields at a late stage of development, alkalis, acids and other reagents are used to increase oil production.

The use of polymers, polymer-dispersed systems and colloid-dispersed systems in oil production worsens the flow of fluid to the bottom of the well in oil-saturated reservoirs and water-flooded zones of the formation, creating conditions for increasing fluid resistance in the formation.

It is necessary to resolve issues that are associated with such features of the oil fields of Azerbaijan, such as the presence of various types of deposits and regimes, weak cementation of reservoirs of the productive strata, and development duration.

For these reasons, most oil reservoirs located on land are exploited with little oil production.

Proper execution and sequence of technological operations at each stage of oil production ensures maximum effect from the entire process, which is expressed in obtaining high-quality oil and maintaining the required production volumes. The maximum effect can be achieved only with high-quality compliance with all technological requirements put forward for this process. Intensification of oil production requires, first of all, a new scientific approach to justify attracting investments into fields and increasing the efficiency of technical and economic processes [2].

II. Methods

I. Enhanced oil recovery (EOR) methods used in the fields of Azerbaijan and abroad

The basis for creating EOR oil-displacing compositions are surfactants of various classes (mainly anionic or nonionic type) in combination with various components (electrolytes, alcohols, hydrocarbons, acids, etc.). For example, a composition for enhancing oil recovery is known, including an anionic surfactant (AS) and a nonionic surfactant (NSAS), where petroleum or synthetic sulfonates with an equivalent weight of 330 to 580 are used as surfactants, and oxyethylated alkylphenols are used as nonionic surfactants. with a degree of oxyethylation from 8 to 16 and additionally - a solvent with the following ratio of components, wt.%: petroleum or synthetic sulfonates with an equivalent weight from 330 to 580...590, ethoxylated alkylphenols with a degree of oxyethylation from 8 to 16...590, the rest - solvent. The disadvantages of this technical solution are the need to use a hydrocarbon solvent and a high concentration of surfactants, which increases the cost of the reagent.

In addition, the composition used in the implementation of the method for developing high-viscosity oil deposits under thermal influence on the formation is known, containing a complex surfactant neftenol VVD (1.0...5.0% wt.) or a mixture of nonionic surfactant (1.0...2.0% wt.) and anionic surfactant (0.5...1.0% wt.), ammonium nitrate (8.0...20.0% wt.), urea (15.0...40.0% wt.), ammonium thiocyanate (0.1...0.5% wt.) and water. In the reservoir, at high reservoir temperatures or thermal effects, urea is hydrolyzed to form an ammonia buffer system [3].

In world oil practice, a composition is used to enhance oil recovery, containing nonionic surfactants and nonionic surfactants, boric acid, glycerin and water. As specified surfactants, the composition contains a complex surfactant, neftenol VVD, or a mixture of nonionic surfactants AF912, or NP40, or NP50 and surfactants volgonate or sulfonal, or NPS6.

Often, gel-forming composites are treated with a water-repellent composition based on cationic surfactants when developing the bottomhole zone of water heating wells (in order to maintain stable reservoir pressure in injection wells and increase the ability to absorb water into the formation). As a result of treatment, the surface of the collector is covered with a monolayer of surfactant molecules, the charged part of the molecules is directed to the surface of the collector, and the hydrophobic part goes into the pore space. Due to the selective orientation of polar surfactant molecules, hydrophobization of the pore space occurs, which prevents intensive coordination interaction of the reagents of gel-forming compounds with the rock surface.

In addition, the disadvantages of the known methods are that an aqueous solution of urea is introduced into a layer with hydrochloric acid to produce an endothermic reaction with the release of heat. A large volume of air is injected into the well, followed by a mixture of steam so that a heat-generating reaction occurs. In this case, the reaction efficiency is not so high. Performing this operation requires a large amount of funds, the resulting result ends with little effect. For these reasons, these methods have not received widespread practical use in the fields.

II. The proposed innovative technology for increasing oil recovery using a "smart" composition

Allows to improve the rheological properties of formation rocks and increase the flow of residual oil to the bottom of the well by reducing its viscosity, changing wetting and surface tension between phases. To achieve this goal, in the first stage, the composition containing methyl alcohol, surfactant (SAM) and water is injected into the layer, which allows to achieve thermochemical effects in the layer. In the second stage, a composition containing a mixture of starch, glue (PVA) and water is injected to form an adsorption layer, create a buffer zone and conduct a thermochemical reaction in the buffer zone. In the third stage, a composition containing a mixture of magnesium, catalyst (Al2O3) and water is injected to carry out the thermochemical reaction in the buffer zone.

The novelty of the proposed innovative technology consists in the implementation of a thermochemical process using the proposed compositions for the creation of an adsorption layer and a buffer zone in the well bottom zone and formation based on a three-stage technology (Fig. 2).

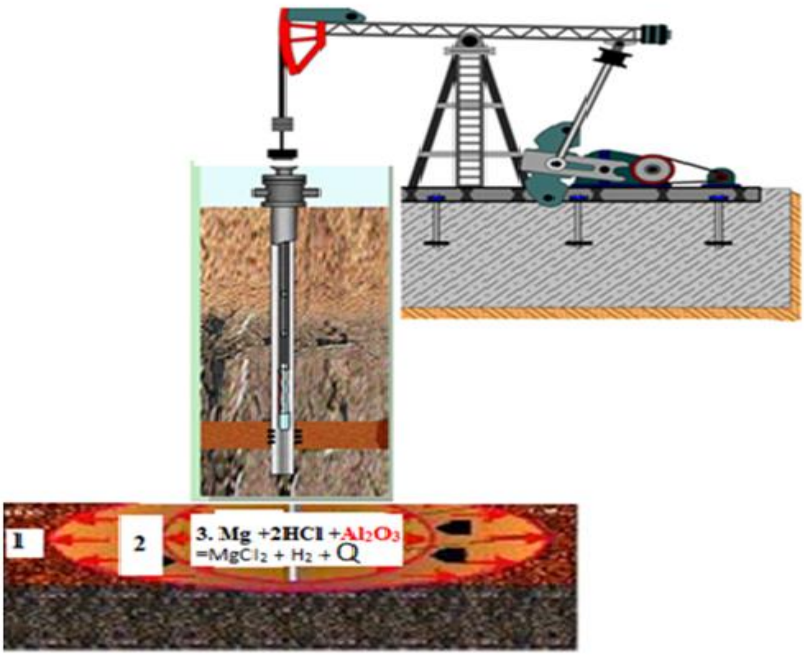

Figure 2: *The scheme of injecting "smart" composition into the well*

Methyl alcohol + SAM + water prepared and injected into the well in the first stage squeezes small particles of sand grains from the bottom zone of the well and washes the oil stuck to the sand rocks. As a result, the viscosity of the oil drops sharply, the flow of oil into the well is improved due to the decrease in surface tension. The fact that oil has a low specific gravity relative to water allows oil to accumulate in the upper part of the formation, and water to enter the lower part of the formation.

The starch + glue + water produced in the second stage creates a buffer zone in the well bottom zone and formation, preventing absorption of magnesium + Al2O3 + water mixture and hydrochloric acid.

In the third stage, a thermal reaction occurs as a result of the encounter of magnesium + Al2O3 + water mixture with hydrochloric acid in the bottom zone of the well.

As a result of the encounter of magnesium + Al2O3 + water mixture with hydrochloric acid in the bottom zone of the well, a thermal reaction occurs. A separate sequential supply of reagents for the implementation of a thermochemical reaction allows to prevent the reaction at the wellhead and inside the well by injecting a surfactant between them [4].

As a result of the reaction, high heat and gaseous hydrogen (H2) compress the methyl alcohol + SAM + water and starch + glue + water counterparts into the formation, enabling the fluid to flow to the bottom of the well. The following thermal reaction takes place in the buffer zone:

$$Mg + 2\,HCI + Al_2O_3 = MgCl_2 + H_2 + Q \quad (1)$$

Here, Q is the heat obtained as a result of the reaction (18.9 Megajoule of heat is obtained as a result of the reaction of 1 kg of magnesium with hydrochloric acid).

The prepared compositions were tested in 6 small production wells of the proposed technology "Bibiheybat" NGCI. The obtained results are shown in Table 1.

As can be seen from the table, the proposed method allows to increase the oil extraction coefficient. Conducting a thermochemical reaction in the well based on innovative technology reduces formation permeability, washes residual oil from formation rocks, separates oil from formation waters, lowers the viscosity of oil inside the formation, eliminates surface resistance, etc. allows to increase the amount of extracted oil due to its improvement.

Table 1: *Results of application of innovative technology*

Indicators	Number of wells			
	3115	3655	3646	3677
	Before the introduction of innovative technology			
Daily oil production, tons	0,5	1,7	0,5	1.2
	After the introduction of innovative technology			
Daily oil production, tons	2,0	3,1	2,0	4,0
Increase in daily oil production, tons	1,5	1,4	1,5	2,8

III. Results

1. On the basis of the proposed innovative technology, based on the works carried out in 3 stages in small oil-producing wells, increasing the permeability of formations in oil wells in operation, a sharp decrease in the viscosity of residual oils in the formation, cleaning the pores from contamination, washing oil stuck to the rock, separating oil from formation water, and the resulting high reaction temperature on the basis of reduction of surface tension, etc. creates an opportunity to increase oil production.

2. To increase the oil recovery of layers, the "smart" innovative composition has high wetting properties. oil-bearing pores.

3. Compared to the reagents in use, PAV has a simple preparation technology and is recommended for use in the oil industry. The price of production of the proposed composition is almost 2 times lower than other reagents produced.

OPTIMIZATION OF THE ECONOMIC POTENTIAL OF THE INDUSTRY ON THE BASIS OF MATRIX ALGORITHM OF DECISION MAKING

Larisa Narkevich
•
Belarusian-Russian University, Mogilev, BELARUS
lora1166@yandex.ru

Abstract

The article is devoted to the issues of modeling the optimization of economic potential of the industry on the basis of matrix algorithm of decision-making. The article considers the algorithm of economic potential optimization based on matrix modeling (state matrices, indicative dynamics matrices, strategic decision-making matrices, matrices of economic potential optimization scenarios).
The adopted modeling format provides systematicity, comprehensiveness, integrity, hierarchy of numerous evaluation parameters, multilevel aggregation of dynamics indices, normalization of sub-indices, point positioning of the level of development of the economic potential of microeconomic systems with the choice of a variant of working out scenarios of strategic priorities of its development.
According to the results of approbation of the model of optimization of economic potential in the information field of the textile industry (Concern Bellegprom), clusters of similar enterprises were identified and variants of working out scenarios of market strategies for optimization of economic potential were developed.

Keywords: economic potential, matrix, dynamics, development, potential-efficiency, index, optimization, strategic scenario, means of scenario development

I. Introduction.

Optimization modeling in the trends of economic potential (EP) development in the industry provides for the development of actual models and methods that provide information-analytical decision support system (IAS DSS). In this direction, the least studied aspects include system interrelations and interdependencies of multifactor modeling of the level of ES development.

The purpose of the conducted research is the algorithmization, methodology and practical tools for selecting the optimal model of effective development of economic potential based on the results of its point positioning in the strategic decision-making matrix of the meso-level.

II. Methods and materials

The author's model of optimization of the EP industry based on a matrix decision-making algorithm is designed on the basis of a systematic, integrated and holistic approach. The EP optimization algorithm included the following steps:

- identification of the goals and objectives of the projected information and analytical decision support system for optimization of EP in the trends of mesorevelopment of the industry;

- carrying out the decomposition of the EP on the basis of structural, process, resource and market (product) approaches with the project of a two-level system of interrelations and interdependencies of indicators of local resource (productive) and institutional potentials (factor);

- formation of a system of indicators for assessing EP in the decomposition of local and private potentials (personnel, production, marketing, innovation and investment, scientific and information potentials);
- construction of matrices of the state of local potentials with an emphasis on the blocks of potential profitability, potential return, potential intensity in a series of dynamics;
- design of indicative dynamic matrices of local potentials with subsequent aggregation of indices of the first and second levels of generalization of potential profitability, potential return, potential intensity (subindexes: Irpi, Iipi, Irp, Iip,);
- point positioning of the level of EP development by integral subindices and the indicator of the third level of generalization (Iep) in the strategic decision-making matrix;
- economic interpretation of interrelations and interdependencies, comparisons, characteristics: identification of imbalances; factors that negatively affected the dynamics of the qualitative state and quantitative development of the EP;
- an extended study of individual structural elements of the EP with detailed factor parameters in particular efficiency matrices in the specific object analytical environment of microeconomic systems of the industry;
- development of options for working out scenarios for optimizing EP at the meso-level; building a vector of priorities for optimizing the sustainable development of EP of industry enterprises with the distribution of public-private partnerships;
- analysis of the compliance of indicators with the objectives of optimization of EP using perspective diagnostics of the effectiveness of decisions made in the reverse order of analytical procedures.

The distinctive features of the industry's EP optimization model based on a matrix algorithm consist in the continuity of the decision–making process: ensuring the consistency, complexity, integrity of a multidimensional, dynamic phenomenon - the economic potential inherent in economic systems; the implementation of structural, process, resource and market methodological approaches in the procedure of its decomposition; a qualitative assessment of the development of the EP, built in the matrix field of efficiency and allowing to establish the relationship and interdependence between the resource potential and the institutional potential ensuring its effectiveness; solving the problem of multi-criteria convolution at several levels of generalization in the construction of aggregated indices, which ensures the point positioning of the level of development of the EP in the strategic decision-making matrix; the formation of relationships and interdependencies in the format of induction, deduction with a vector of priority growth of the effectiveness of the EP in the long term both in its individual elements (the method of private matrices) and the EP as a whole in the context of sustainable development, structural optimization.

III. Literature review

Today, multidimensional scientific developments have been formed within the framework of optimizing the economic potential of enterprises. The theory of determining economic potential from a general theoretical standpoint is studied in the works of Malinovskaya (2006); Kleiner (2008). Many scientists dealing with the problems of economic potential consider this category as part of improving the efficiency of the national economy: Shimov (2012), Lapin (2006). The most common is the resource approach to determining economic potential, which is supported by scientists: Khanov (2007); Vinogradova et al. (2008); Malinovskaya (2008); Timofeeva (2009).

The studies of Kiseleva (2012), Ryazantseva and Aristarkhov (2012) determined the ability of an enterprise as a socio-economic system not only to achieve results in its current state, but also to fulfill strategic goals of sustainable development. The system of functions of the economic potential of the economic system has received theoretical development in the works of such scientists as Medvedeva et al. (2014), Nadvornaya et al. (2016), Artemyeva (2010).

Various aspects of the dynamism of economic potential are studied in the works of Rafikova

(2006); Babaeva et al. (2015); Nekozyreva (2008); Vrublevsky (2016).

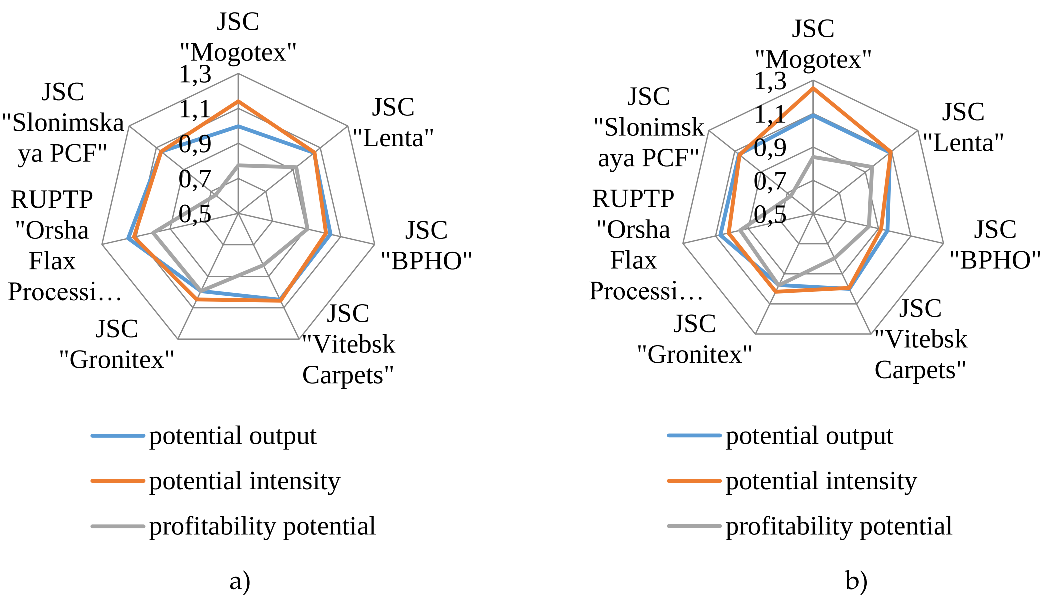
Some methodological aspects of economic potential assessment have been studied by scientists: Afinogenov et al. (2019), Khvorostov (2005), Gorbunova (2014), Vapne (2019), Gonin et al. (2014),), Sheshukova et al. (2013), Shcherbakov et al. (2019), Kovalev et al. (2006), Morozova (2009), Mogilina (2015), Nizamutdinov (2017), Peshkova (2017), Pisareva (2018), Rakhmanova (2018), Tashkinov (2018), Terekhova-Pushnaya (2019), Podolsky et al. (2020), Yarygina (2016), Gurieva (2018), and others.

At the same time, despite a sufficiently deep and thorough level of scientific elaboration of theoretical directions for optimizing economic potential, management science involves the development of key provisions of mathematical modeling of EP optimization procedures in modern conditions of globalization and international integration of national economies to solve many relevant theoretical, methodological and practical problems. Among the most important theoretical, methodological and practical directions of EP management are: the formation of the concept of optimizing economic potential at all levels of management in the context of economic globalization; the development of conceptual models of EP optimization that ensure consistency, complexity, program-target orientation of EP optimization strategies.

IV. Results and discussion

Approbation of the model of optimization of ES on the basis of the matrix algorithm of decision-making was carried out in the methodological blocks of information processing for the leading enterprises of the textile industry. Analytical calculations of private indicators of efficiency of local potentials use with the subsequent convolution and calculation of generalizing indices of potential-efficiency were made for strategic enterprises of Concern “Bellegprom”: JSC “Baranovichi Production Cotton and Paper Association” (Blakit; JSC “BPHO”), JSC “Gronitex”, RUPTP “Orsha Flax Factory”, JSC “Mogotex”, JSC “Lenta”, JSC “Vitebsk Carpets”, JSC “Slonimskaya KPF”.

According to the results of the analytical data system, the following conclusions can be drawn: the best results of the level of ES development in the considered time interval were demonstrated by RUPTP “Orsha Flax Mill”, JSC “Gronitex” (Figure 1).



a) aggregate indices of the first level of generalization of resource potential;
b) aggregate indices of the first level of generalization of institutional capacity

Figure 1: *Graphical interpretation of the partial values of the potential efficiency of the enterprises of the Bellegprom Concern*

Source: in-house development

Coordinates of the index of potential profitability of enterprises respectively made up in the composition (1.0; 0.994); (0.948; 0.976), which, taking into account the significance coefficient, provided higher values of the integral index (values of aggregated indices are higher than one). RUPTP "Orsha Flax Factory" is the only enterprise that has an integral aggregated index of the level of economic potential development with a small excess of one (Figure 2).

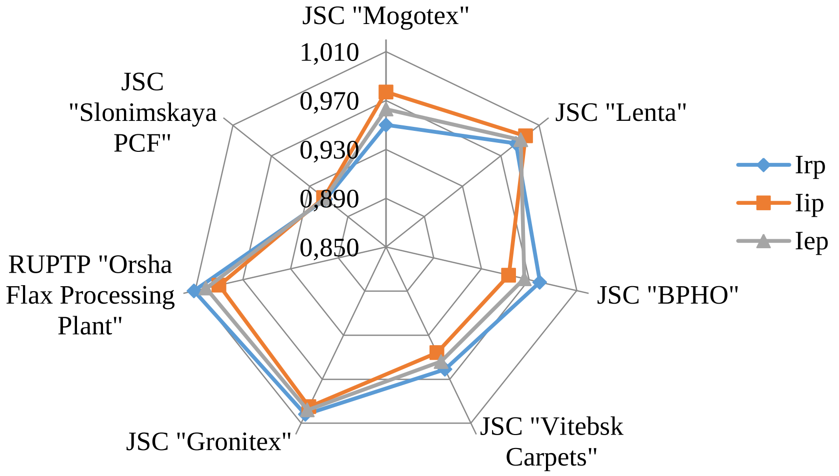


Figure 2: *Radar of the level of development of the economic potential of the enterprises of the Bellegprom Concern*

Source: in-house development

The lowest values of the considered aggregated indices were obtained for JSC «Slonimskaya PCF», JSC «Vitebsk Carpets», JSC «Mogotex», JSC «BPHO»: the aggregated index of the third level of generalization, respectively, amounted to 0.914; 0.954; 0.963; 0.966.

The integral indicator of the efficiency of using the economic potential of JSC «Lenta» (0.991); JSC «Gronitex» (0.998) has almost reached the criterion value.

The analysis of the dynamic series of indexed estimated parameters of the use of EP according to the selected vectors of its development diagnoses: the level of effectiveness of its use according to private indices of potential efficiency within the framework of local potentials; trends in the parameters of the effectiveness of the use of local potentials; development priorities according to criteria of potential efficiency; the need for preventive measures to optimize EP in order to prevent a crisis in the results of the system (Table 1).

Table 1: *Summary of average annual performance indicators for the first section of the output array of aggregated indices of textile industry enterprises*

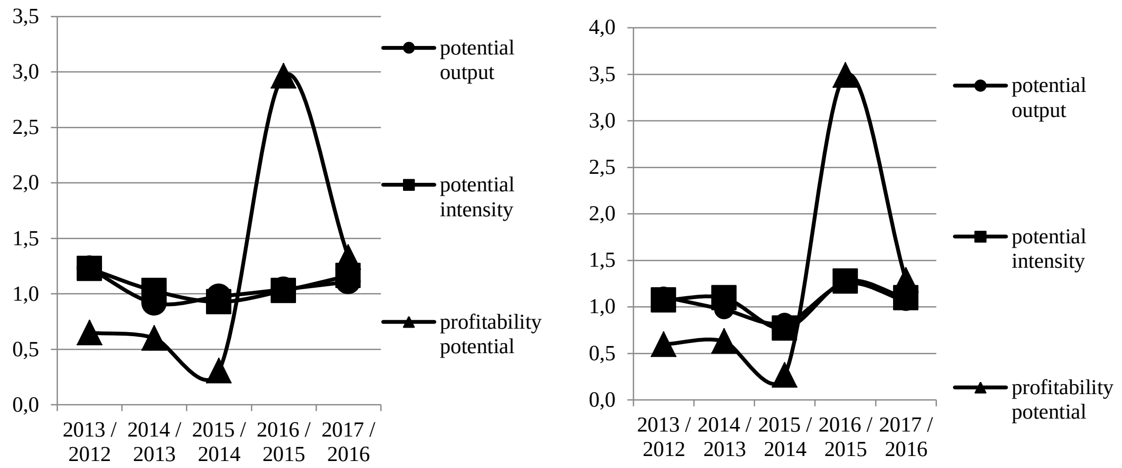
Dynamics comparison form	Local resource potential			Local institutional capacity		
	potential output	potential intensity	profitability potential	potential output	potential intensity	profitability potential
2013 / 2012	1,229	1,228	0,650	1,108	1,072	0,599
2014 / 2013	0,917	1,027	0,602	0,970	1,095	0,630
2015 / 2014	0,976	0,928	0,310	0,826	0,768	0,268
2016 / 2015	1,040	1,028	2,965	1,251	1,273	3,490
2017 / 2016	1,109	1,163	1,332	1,062	1,095	1,288
Average annual index	1,049	1,070	0,863	1,034	1,047	0,854

Source: in-house development

The lowest index values in the selected time interval fall on the profitability potential:

respectively, according to the local potentials of 2015 / 2014 in the amount of 0.310; 0.268. Accordingly, 2016 marked a significant increase in profitability potential: index values within the composition of 2.965; 3.490.

In 2016-2017, the level of indices of local resource potential is lower than the values of indices of potential return, potential intensity, potential competitiveness of local institutional potential, which corresponds to a decrease in the volume parameters of resources and expenditures of the providing potential and a corresponding increase in these efficiency fields (Figure 3).



a) b)

Figure 3: *Diagram of the level of development of the potential efficiency of the Bellegprom Concern in the cluster of selected enterprises: a) resource potential; b) institutional potential*

Source: in-house development

The average annual index of potential return and potential intensity for 2012-2017 in local potentials were marked by growth indices, while potential profitability decreased (average annual decrease indices 0.863; 0.854). Taking into account the importance of the considered parameters in the decision support system, the average annual index of changes in economic potential as a whole was marked by a decrease.

The average annual index of potential return and potential intensity for 2012-2017 in local potentials were marked by growth indices, while potential profitability decreased (average annual decrease indices 0.863; 0.854). Taking into account the importance of the considered parameters in the decision support system, the average annual index of changes in economic potential as a whole was marked by a decrease. The combined average annual index has a value above one for potential output, potential intensity: values of local resource potential (1,049; 1,070) above the level of local institutional potential (1,034; 1,047); the level of positioning of potential profitability is lower than the first two parameters and is almost the same for local potentials (0.863; 0.854). Analytical support for solving optimization problems at the industry level in the developed EP optimization model is based on the synergy of blocks of composition of aggregated indices of the second and third levels of generalization (Table 2).

In this block of analysis of the dynamics of the level of use of resource and institutional potentials of textile industry enterprises, an imbalance has been established, which was expressed in a more intensive development of potential output, potential intensity, potential profitability of the providing component of the composition – institutional potential. The aggregated indices on the right side of table 2 (the results of the institutional capacity analysis) indicate higher values of the development indices relative to the data of the local resource potential. For individual enterprises, for example JSC «Mogotex», the level of development of potential output, potential intensity, potential profitability of institutional potential is higher than similar indicators of resource potential, which corresponds to higher growth rates of production, sales, profit from sales relative to the costs of marketing activities, innovation– investment and scientific and information activities. The cluster of these enterprises also includes JSC «Lenta», JSC «Slonimskaya PCF».

Table 2: *The second section of the output array of aggregated indices of the second and third levels of generalization of the economic potential of enterprises in the textile industry*

The enterprise of the textile industry	Resource potential subindex	Institutional subindex capacity	Integral aggregated index of the level of development of the EP
JSC «Mogotex»	0,950	0,977	0,963
JSC «Lenta»	0,986	0,996	0,991
JSC «BPHO»	0,979	0,953	0,966
JSC «Vitebsk Carpets»	0,961	0,946	0,954
JSC «Gronitex»	1,002	0,995	0,998
RUPTP «Orsha Flax Processing Plant»	1,011	0,990	1,001
JSC «Slonimskaya PCF»	0,913	0,915	0,914

Source: in-house development

For all the studied enterprises of the textile industry, low values of integral indices of potential profitability were determined, which corresponds to a less intensive dynamics of profit growth from sales relative to production capital and fixed costs. The lowest values of the indices of profitability dynamics of resource and institutional potentials were noted for JSC «Slonimskaya PCF», JSC «Mogotex», JSC «Vitebsk Carpets»: the profile of integral indices of potential profitability of resource potential 0.667; 0.774; 0.830; institutional potential 0.671; 0.839; 0.795. The EP optimization system should provide for monitoring and controlling pricing in terms of profit generation as a source of own financing for extensive and intensive factors of positive EP development. Aggregated indices of potential output, potential intensity of textile industry enterprises are almost at the same level in both blocks of the composition. Certain «scissors» of the indicated indicators were obtained at JSC «Mogotex», which is due to the export orientation of production, the influence of external factors of globalization and international integration.

The format of the point positioning of the level of economic potential development was obtained based on the results of linear normalization of aggregated indices of the second level of generalization (Figure 4).

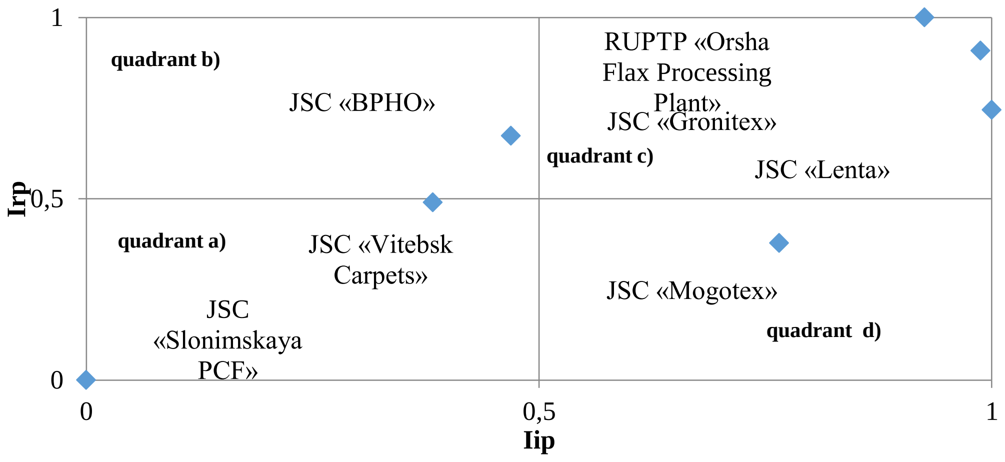


Figure 4: *Positioning textile industry enterprises in the strategic decision-making matrix*

Source: in-house development

According to the results of econometric estimation of interrelation of sub-indices (Irp, Iip) of the level of formation, use and development of economic potential of textile enterprises, the matrix of scenarios for optimization of the meso-level EP (textile industry) is constructed and variants of working out scenarios are established.

V. Conclusion

Thus, the developed model of optimization of the EP industry based on a matrix decision-making algorithm has the properties of complexity and integrity, which make it possible to substantiate the role and place of the process of optimizing economic potential in the trends of mesorevelopment, to determine the content of decision support processes for the sustainable development of the meso-level economic system.

The coordinates of the point positioning of the level of development of the EP enterprises of the textile industry made it possible to identify clusters of similar enterprises and develop options for working out scenarios. For example, JSC «Gronitex» and JSC «Lenta» (coordinates of points before normalization, respectively (1,002;0.995); (0.996; 0.986)) occupy approximately the same position in the subindex of local institutional potential: the aggregated index of resource potential is lower than the institutional one as a result of an insignificant parameter of potential profitability (with a high coefficient of significance when integrated) in the structure of the index of economic potential.

For these enterprises, it is advisable to implement elements of centered diversification strategies (SD-1) with an emphasis on investment and innovation activities in the production of new products based on the use of modern organizational and technological tools of the company's operational activities; the implementation of the most effective innovation and investment projects to reduce production risks.

Abstract

The work analyzes the fire hazard categories of oil field facilities. It is shown that the analysis of the results of an accident with the release of all contents from an oil tank and calculation of the average release, and therefore the damage, reveal an 8.8-fold deviation from that adopted by the regulatory document. A fireball, as in the development of an accident, at oil field development sites cannot be realized, because properties of the products are incapable for instant evaporation even under preheating conditions.

Keywords: oil, reservoir, accident, thermal radiation, danger level, probable damage, spill diameter, fireball

I. Introduction

In case of fire, the parameters of the intensity of thermal radiation and the duration of exposure are used to determine the level of danger. The methodology for determining individual risk in a fire is presented in [1]. The safe level of thermal exposure to a person is determined by the intensity of thermal radiation not exceeding 4 kW/m^2. With a significant potential of the flammable liquid involved in the fire, the probability of injury to a person remote from the spill boundary is zero. A fire represents a process that results in a long-term realization of the potential of a combustible substance, in contrast to an explosion, in which the realization of the potential is fleeting process. Depending on the speed of ongoing processes, their power varies significantly. The greater the speed, the greater the power of implementation, and the losses (human and material). Analyzing fire as a process, we come to the paradoxical conclusion that flammable liquids do not burn. Their combustion is truly impossible, since it is an oxidation-reduction process, which is impossible inside a liquid. There is no oxidizing agent. The combustion of a liquid is a rather complex process, consisting of several successive stages. In relation to oil, which consists of a large number of hydrocarbon components, characterized by different boiling points and levels of saturated vapor pressure, the combustion process has its own characteristics. The main stages of this process are as follows: Heating of the liquid in order to increase the vapor pressure. Heating of the liquid must ensure its such a temperature in which a gas-air mixture with a concentration of flammable substance above the its surface is formed above its LCLC. An external ignition source ensures ignition of the mixture. The combustion of the gas-air mixture above the surface of the liquid ensures its further heating and intensifies the process of vapor release. The top layer of liquid warms up and combustion intensifies. At the initial stage of combustion, the lightest components evaporate from oil, the boiling point of which is significantly lower than the ambient air temperature. With the start of combustion, the process of oil distillation begins, as a result of which the lightest components pass into the vapor phase (and burn there), while heavier components accumulate in the liquid residue. The boiling point of the remaining components increases as the light components evaporate. If the onset of combustion corresponds to an oil temperature of 20°C, then after a certain period of time it increases to 60, 100°C, reaching a temperature of 300-400°C at the end of the process, when components with a high boiling point have accumulated in the residue. In case of tank fire, the water layer poses a serious danger. Water is always present in oil in small doses. Under the influence of gravity, it settles to the bottom of the tank and accumulates there to significant volumes. It is under excess pressure from the top layer of oil. By the end of burnout, the oil temperature reaches 300-400o C. The water heats up over the area of contact with the oil, reaching temperatures above 100° C. A further decrease in the oil level in the reservoir leads to rapid overheating of the water. The water instantly boils, a steam-water piston is formed, which throws burning oil out of the tank. A cloud of dispersed burning liquid is formed, which is thrown onto the surface of the earth, destroying all living things. Such a development of the accident is accompanied by a large number of people affected not only at the hazardous production facility, but also beyond. To protect tanks from fire, regulations require them to be equipped with stationary foam generators. According to the State Fire Service of the Nizhnevartovsk region, over 15 years, not a single case of successful protection has been recorded during fires in tanks equipped with foam generators. Foam generators failed at the initial stage of fire development, as a result of which all tanks burned out completely. Let us consider the fire parameters depending on the size of the evaporation surface. For example, we select a tank with a volume of 5000 m3, filled with oil, placed in an embankment. The diameter of the tank is 23 m, the height is 12 m. The dimensions of the embankment are 33x33 m. The release of the specified volume of oil onto the terrain without embankment provides an area of evaporation (at a specific oil consumption of 10 l/m2) of 500000 m2. The results of calculating the radius of the affected area R1 are presented in Table 1.

Table 1: *The results of calculating the radius of the affected area R1*

Fire option, Pa	Evaporation square, m^2	Mirror diameter, m	Flame height, m	Radius of the affected area, m
In the tank	415.5	23	22.23	11.5
In the embankment	1088	37.23	31.1	18.62
Unlimited surface	100137.5	357.07	149.54	178.54

Table 1 analysis of the results of calculating the parameters of a fire occurring under conditions of different restrictions revealed the effectiveness of localizing an oil spill in an embankment. The radius of the affected area is reduced by 9.6 times. Here is another example of the realization of the same potential under different conditions. Due to the results of implementation are the most dangerous fire balls (fire- in the terminology of V. Marshall [2]), as a type fire. GOST R 12.3.047-98 [3] defines a fireball as a large-scale diffusion flame of a burning mass of a fuel vapor cloud rising above the surface of the earth. Many protect institutes determine the parameters of fireballs and their consequences when developing projects for the development of oil fields. The main condition of the occurrence of a fireball is a salvo release of liquefied gas capable of instantaneous evaporation under atmospheric conditions in an amount of at least 35% of the mass. The specified conditions can be implemented when releasing liquefied gases (propane, butanes, and their mixtures). An oil release cannot lead to instantaneous evaporation of a significant mass, because the proportion of highly volatile components in it that are capable of release under ambient conditions environment, does not exceed 1% of the mass. Until the fields begin to create installations for processing APG with the release of natural gas liquids or propane-butane fraction, there risk of fireballs are excluded. Due to the lack of results from studies of fireballs carried out by Russian scientists, to substantiate our position we use the information presented in the book by Marshall B [2]. Conditions for the formation of this powerful phenomenon are presented in Table 2.

Table 2: *Conditions for the formation of this powerful phenomenon*

Classification of flammable substance on Marshall	Example	Flash point, ^0C	Vapour pressure, 20 ^0C, atm	Vapour fraction, mass	Probability of occurence		
					Flash	Fire spill	Fireball
Flot liquid	Lubricating oil		0.0001	Insignifica nt	Zero	Only in case of fire	Low
Flammable liquid	n-xylene	40	0.008	0.0005	Zero	High	Low
LFL	Octane	13	0.013	0.0015	Moderate	High	Low
LFL	Diethylene	45	0.58	0.024	High	High	Low
Cryogenic liquid	LHG	Low minus 160	0.1 (-160 ^0C)	0.04	High	High	Low
Liquefied flammable gas	LHG (propane, propylene, butane)	-107	1	0.4	High	Sometim es there is no liquid phase	High
Compressed flammable gas	Methane, Ethane, ethylene			1.0	High	Zero	High

As follows from the analysis of the data presented in the table, a fireball is realized when at least 40% of the mass of liquid gas or superheated liquid evaporates. Combustible liquids and flammable liquids do not form a fireball. Let's consider another example of the implementation of regulatory instructions: When determining the volume of emission from a unit during its complete depressurization, the standards require choosing the most unfavorable case in all respects. Let's consider the result of an analysis of an accident involving the release of all contents from an oil tank. The field tank performs the function of protecting external consumers from the issuance of substandard products. The reservoir operation cyclogram is shown in Fig. 1.

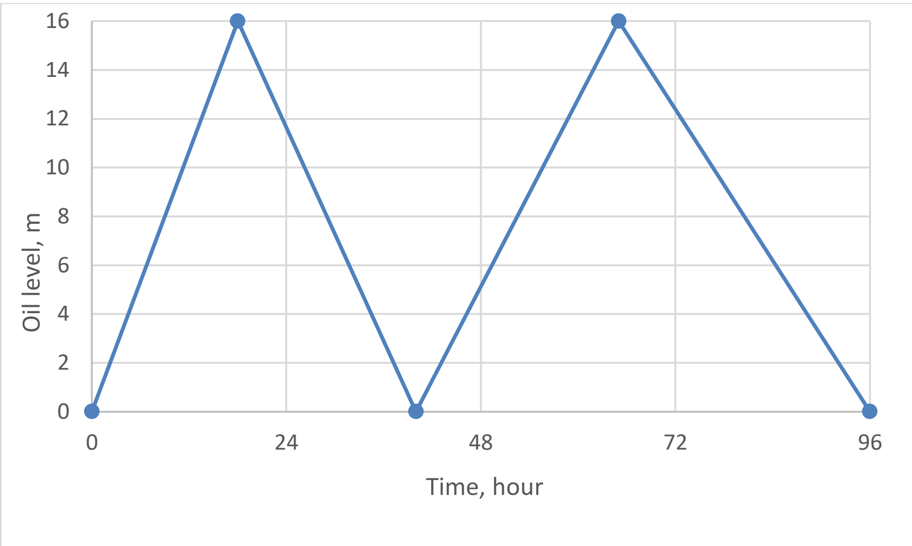

Figure 1: *Tank operation cyclogram*

The tank is filled within 24 hours. At the same time, quality control of commercial products is carried out. If the quality meets the requirements of the technical specifications, the tank switches to pumping oil into the main oil pipeline. Pumping continues for 24 hours. After this, the cycle is repeated. Guided by the requirements of air safety regulations, in case of emergency depressurization of a tank in the consequences of an accident, its entire volume must be taken into account. From the analysis of the cyclogram it follows that the lifetime of the maximum level is zero. The calculation of accident indicators should be carried out using statistical methods based on the laws of probability theory. The probability of 100% filling of the tank is determined by the ratio of the duration of existence of this filling to the duration of the cycle. In our example, the lifetime of 100% occupancy is zero. The cycle duration is 48 hours. Dividing zero by 48, we get the probability of such filling equal to zero. Taking into account 100% filling of the tank during an accident in a probabilistic representation will give a zero result of damage. To determine the average statistical volume of flammable liquid released onto the terrain in such an accident, we will draw up a table that determines the level of probable damage depending on the percentage of the tank being filled. Of course, the maximum or minimum filling of the reservoir correspond to a probability equal to zero, since in both cases the duration of extreme filling is zero. With a filling fraction of 0.5, the duration of this state is 0.5 and soon. Tank statistics at throughout the entire cycle of its work are presented in Table 3.

Table 3: *Tank statistics at throughout the entire cycle of its work*

Tank fill percentage	Filling probability	Probable damage	Normalized damage
1	0	0	1
0.9	0.1	0.09	1
0.8	0.2	0.16	1
0.7	0.3	0.21	1
0.6	0.4	0.24	1
0.5	0.5	0.25	1
0.4	0.4	0.16	1
0.3	0.3	0.09	1
0.2	0.2	0.04	1
0.1	0.1	0.01	1
0	0	0	1
Total	2.5	1.25	11
Average value	0.227	0.114	1
Ratio of average damage values		8.8	

II. Methods

All data is presented in relative units. It turned out that the calculation of the average emission, and therefore the damage, revealed an overestimation of the Damage accepted by the regulatory document by 8.8 times. We encounter such "errors" in almost all elements regulatory calculations approved "in accordance with the established procedure". The maximum value of the emission volume, determined according to the laws of statistics, turns out to be equal to 0.5 of the tank volume. This condition corresponds to an arithmetic average filling volume of 0.5 and a maximum probable damage value of 0.25. The average value of probable damage is 0.114. To determine the size of a flammable liquid spill, there are 3 methods in the current methodological and regulatory documents: FSS 105-03 [3-6] determine the area of a liquid spill using a specific flow rate of 10 l/m^2. Thus, the area of spill

$$F=100V \quad (1)$$

Where, F is measured in m^2, and the volume of the spill V in m^3. The spill diameter is determined from the equation area of the circle, that is

$$D= (4F/\pi)\ 0,5 \quad (2)$$

The RSES methodology [1] determines the spill diameter using the equation

$$D = (25,5\times V)0,5 \quad (3)$$

The methodology for risk analysis of main oil pipelines (MOP) [5] determines the spill area according to the equation

$$F=53,3\ (V)0,89 \tag{4}$$

The spill diameter is determined by equation (2). A comparison of the results of calculating the diameter of the spill, performed using the specified methods, is presented in the graphs of Fig. 2.

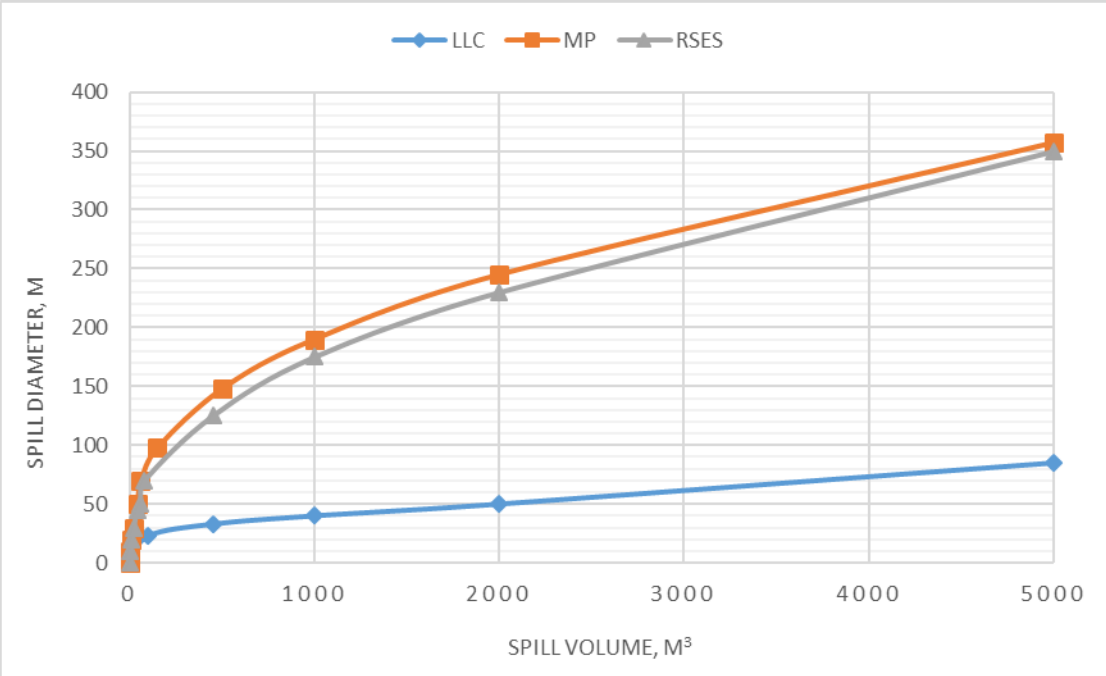

Figure 2: *Comparison of spill diameter due to various methods*

The compared methods have the status of normative documents. The result of calculating the diameter of a flammable liquid spill using various methods is different. The question arises, which of these methods should be preferred?

Where is the guarantee that the methodology chosen by the project organization will coincide with the choice of the expert organization. If different methods are used when developing the "Risk Analysis" section and during its examination, then the results should be considered "non-reproducible". A practical guide for the designer is that if there are several guidance documents on the same issue, any one of them can be used. The fact that the choice of the expert does not coincide with the choice of the project organization is not a problem for the project institute. This is a problem for developers of regulatory documents. As it follows from the analysis of the data presented in the table, a fireball is realized when at least 40% of the mass of liquid gas or superheated liquid evaporates. Combustible liquids and flammable liquids do not form a fireball.

III. Results

1. The fire hazard category of oil field facilities is determined by standards based on the indicators of explosion of gas-air mixtures.

2. Analysis of the results of an accident with the release of all contents from an oil tank and calculation of the average release, and therefore the damage, reveal an 8.8-fold deviation from that adopted by the regulatory document.

3. A fireball, as in the development of an accident, at oil field development sites cannot be realized, because properties of the products are incapable for instant evaporation even under preheating conditions.

Abstract

The article examines from an interdisciplinary perspective the problem of quantitative accounting, assessment and minimization of the carbon footprint (CF) of the infrastructures of the oil and gas sector (OGS) of the fuel and energy complex (FEC) of Russia at all stages of their life cycle (LC), including diagnostics, monitoring, maintenance, recovery from accidents and disasters. The ultimate goal of the study is to develop a working algorithm that allows formulating a global carbon balance equation according to the top-down scheme, which shows the contribution of each infrastructure to the global carbon footprint, taking into account climate change according to the criterion of the need to achieve zero CO_2 emissions by 2060, in accordance with the obligations assumed by Russia under the Paris Agreement of 2015.

Keywords: global warming, global carbon budget, greenhouse gas emissions, carbon footprint of infrastructure, decarbonization, carbon offsetting.

I. Carbon Footprint of the Oil and Gas Industry: State of the Art

The oil and gas industry is not the most important emitter of greenhouse gases (GHG), operations for the extraction and production of hydrocarbon fuels (HCF) account for only 10 % of global emissions. However, further use of HCF provides an additional 33 % of emissions in end-use areas. Over the entire cycle from extraction to end-use, 57 % of GHG emissions from oil are concentrated in the transport sector; in gas, 72 % of emissions occur in generation, industry and public utilities. In the extraction, processing and transportation of oil and gas, methane plays a significant 42 % role, associated with the extraction of natural gas and associated petroleum gas, as well as the transportation of dry stripped gas [1].

In terms of hydrocarbon fuels, most companies agree that in the baseline scenario, the energy transition will not lead to an absolute reduction in demand in the next 10–20 years. Thus, according to forecasts, oil consumption by 2030 will grow by 0–15 % compared to 2019, while gas demand will grow at least until 2040 within the range of 25–52 % [1].

To date, all major Russian oil and gas companies have implemented carbon management systems, including greenhouse gas emission accounting systems. When preparing reports on greenhouse gas emissions, the national methodology for quantifying GHG emissions approved by the order of the Ministry of Natural Resources and Environment of the Russian Federation dated 27.05.2022 No. 371 [2] is used, as well as foreign guidelines: the corporate standard for accounting and reporting of the Greenhouse Gas Protocol (GHG Protocol) of the World Business Council for Sustainable Development and the World Resources Institute [3], the international standard ISO 14064-1:2018 "Greenhouse gases. Part 1: Specification with organization-level guidance for quantifying and reporting greenhouse gas emissions and removals" [4].

All major Russian companies provide data on GHG emissions as part of their periodic reporting (environmental report, or as part of a sustainable development report or annual report). The total GHG emissions in the oil and gas sector of the Russian economy in 2019 amounted to 297.6 million tons of CO_2-eq., the total GHG emissions of the largest companies in the sector (PJSC Gazprom, PJSC Rosneft, PJSC LUKOIL, PJSC Gazprom Neft, PJSC Surgutneftegaz, PJSC Novatek, PJSC Tatneft and PJSC Transneft) amounted to 236.2 million tons of CO_2-eq. [1].

II. Statement of the problem

For a qualified and consistent assessment of the ecological/carbon footprint of the OGS of the Russian fuel and energy complex, it is necessary to conduct a specific analysis of their full life cycle (FLC) to assess (1) the value of the carbon footprint of the OGS as a random function of time and (2) its contribution to the industry's CF, which affects climate change on the planet.

The full life cycle of any OGS infrastructure (OGI) consists of: (1) extraction of raw materials required for the creation of this infrastructure; (2) processing of materials, manufacturing of the OGI components; (3) construction of infrastructure; (4) hydro testing of the OGI pipeline to check for defects; (5) operation of the system, including its diagnostics, monitoring and scheduled maintenance; (6) restoration of the infrastructure after each accident and (7) its disposal after its useful life.

The carbon footprint of OG infrastructure is an indicator of the environmental efficiency of its use at all stages of its life cycle, and is therefore of great interest to the public and investors. Decision makers (DM) on the methods of operating OGI should (in the context of the Paris Agreement) separately take into account the size of the current and cumulative CF they create and the discounted cost of its neutralization, taking into account the impact of climate change on the CF of OG infrastructure.

In the conditions of dynamic multifactorial uncertainty of the modern world, OGI management is carried out according to safety and risk criteria – determining indicators of the quality of their functioning. In this case, the target function (TF) of risk management is reduced to minimizing the generalized cost of operating an OGI facility over the period of time “from conception/cradle to grave”.

From a mathematical point of view, the problem of managing the risk of OGI is posed as a problem of optimizing the objective function, which in the context of the problem under consideration should adequately reflect the total present value of costs during the entire life cycle for:

1) creation and disposal of OGI;
2) technical maintenance, repair and restoration due to possible emergency situations;
3) restoration of the disturbed (due to the production activity of the system) ecological balance of the environment;
4) compensation for the system's CF; and
5) restoration of lost human health and monetary compensation for the possible loss of lives and limbs during the operation of OGI.

In the most general case, the problem of determining the man-made risk, interpreted as the product of the probability of failure (POF) and its consequences (losses/damage), expressed in monetary form, is solved as a problem of optimizing the target function of managing the risks of operating the OGI, which is reduced to the integral cost of owning the OGI over its full life cycle:

$$ {}_{\mathrm{OGI}}C_{\Sigma} = C_{\Sigma,c} + C_{\Sigma,in} + C_{\Sigma,r} + C_{\Sigma,cf} + C_{\Sigma,hl} \,. \quad (1) $$

Here $C_{\Sigma,c}$ is the total cost of design, construction and commissioning of the OGI, as well as its disposal after the end of its service life; $C_{\Sigma,in}$ is the total cost of all inspections on the OGI life cycle; $C_{\Sigma,r}$ is the total cost of all repairs/restorations during the life cycle of the OGI, including after accidents and disasters; $C_{\Sigma,cf}$ is the total costs of compensation for damage from CF; $C_{\Sigma,hl}$ is the cost of restoring lost human health and the amount of monetary compensation for possible loss of lives and limbs during the OGI life cycle.

When solving the problem of assessing and minimizing the CF size, it is necessary to take into account following circumstances.

The size of the CF when creating the OGI is determined by the facility design goals; at the same time, the CF size is subordinated to these goals and cannot be a limiting factor. It follows from this that compensation for the CF caused by the construction and commissioning of the OGI may require the use of special financial instruments (for example, planting a certain number of fast-growing and highly CO_2 absorbent tree species). At the same time, the size of the CF when utilizing such an OGI is also a certain function of its original goal.

The main carbon plume occurs during the operation of the OGI. It is a function of the volume and quality of diagnostics, monitoring, pipeline maintenance, as well as the consequences of OGI depressurization as a result of incidents, accidents and disasters.

Since all these operational events are modeled when constructing a set of OGI life cycle scenarios required to assess and minimize operational risk, the value of the CF is obtained as a natural consequence of the scenario under consideration. In this case, minimization of the CF for each virtual violation of the integrity of the pipeline or OGI vessel is possible in the process of making the next decision. This allows for effective management of the size of the carbon plume by selecting the optimal system design and optimal inspection technologies, scheduled repairs, and restoration of OGI after depressurization or an accident.

III. General algorithm for assessing the carbon footprint of OGI

Consider the general algorithm for assessing the carbon footprint of the OGI throughout its life cycle.

Since the sectoral CF is formed by individual infrastructures of companies/states, in order to reduce it, it is necessary to strive to reduce its carbon emissions at the level of each infrastructure, starting from the initial stage of the OGI life cycle – the production of its structural components and the construction itself. By analogy with the name of the life cycle stage, we will call the emissions of this stage the initial CF of the OGI.

The calculation of the natural gas transportation efficiency factor takes into account methane (CH_4) and carbon dioxide (CO_2) emissions, as well as energy consumption per unit of production generated at all stages of its life cycle. The share of other greenhouse gases (GHG) is no more than 1 % of all GHG emissions and they are not taken into account in the quantitative determination of the efficiency factor.

The OGI life cycle consists of the following stages:

I) production of materials from which the components of the OGI will be manufactured (extraction of raw materials for the production of structural materials is usually not considered in the calculation of the CF);

II) production of structural components of the OGI;

III) transportation, welding, laying of the OGI pipeline string and its protection from external influences, installation of all process equipment;

IV) operation of the OGI in a stationary mode, including scheduled and unscheduled diagnostics, technical repairs, maintenance;

V) processing/disposal of the OGI components after completion of its operation.

Now consider in general terms what the OGI's CF consists of and how it is calculated at each stage.

Stage I. Production of materials for the manufacture of components

At the stage of production of materials, the CF depends on the type of materials from which the structural components of the OGI are made, their weight and the GHG emission factors during the production of these types of materials.

$$CF_{\mathrm{I}} = \sum_i EF_i m_i \ , \tag{2}$$

where EF_i is the emission factor for the production of the i-th material; m_i — mass of the i-th material in the components of the OGI.

Examples include the production of steel or polymers needed to manufacture pipes and pipeline equipment, the production of concrete needed to construct compressor station buildings, the production of anti-corrosion materials used to protect pipes, etc.

Stage II. Production/manufacturing of structural components.

The components of the OGI include: oil and gas valves, taps, gas compressor station (GCS), oil pumping station (OPS), gas distribution station (GDS), gas control point.

At this stage, the energy consumption of the equipment used in the production of OGI components is generated by the energy consumption of the equipment and depends on the type, quantity, power consumption and operating time of this equipment.

$$CF_{\mathrm{II}} = \sum_i \sum_j EF_{ij} w_{ij} t_j \ , \tag{3}$$

where EF_{ij} is the emission factor when using the i-th energy source by the j-th type of equipment for the production of components; w_{ij} is the energy consumed (power) by the j-th equipment per unit of time (hour) from the i-th energy source; t_j is the operating time of the j-th equipment.

For example, in the production of steel pipes, emissions from energy consumption by equipment used to produce sheet steel from finished raw materials, subsequent calibration, stretching, cooling, cutting, welding and other technological processes are taken into account..

For gas (oil) pipelines, emissions from anti-corrosion coatings of pipe surfaces with special materials are also taken into account, which also have their own emission factors, and the emissions will depend on the area, thickness and density of these coatings. Emissions from the production of materials included in the coatings are calculated using formula (2), and from the coating process using formula (3).

Carbon emissions in OGI increase with increasing pipeline throughput: larger pipe diameters and wall thicknesses require more steel at the production stage.

The production of oil and gas pumping and other process equipment is also accompanied by carbon emissions, and OGI emissions at the stage of production of its components will depend on the design number of equipment of these types and are calculated based on the weight of the equipment and the average emission factor of the manufacturing industry in the region..

Stage III. Transportation to the site, welding, installation and laying of the pipeline and its protection from external influences, construction of compressor stations, oil pumping stations and other structural components of the oil and gas pipeline system.

The carbon footprint at this stage is calculated similarly to stage II, taking into account all types and quantities of energy-consuming machinery and equipment involved in the construction of the facility, and the time spent on their operation. For the construction of the OGI, it is necessary to perform:

- geological and geodetic studies of the area, preparatory work along the pipeline construction route (clearing vegetation, leveling the land plot, installing temporary roads for moving the construction equipment);

- transportation of OGI components and equipment to the construction site – pipes, pumps, compressors, shut-off valves, gas instruments, control and measuring devices, support structures, materials and structures for constructing a compressor station or a pumping station;
- excavation works for laying underground pipeline strings in trenches or construction of supports, columns, overpasses for ground oil and gas pipelines, measures to strengthen the soil and enhance its stability, construction works for the construction of industrial buildings and structures, installation of all technological units of the oil/gas pipeline;
- removal of construction waste;
- hydraulic testing, checking the tightness and functionality of systems and equipment before putting the entire system into operation.

Execution of all these works for the construction of an oil and gas pipeline require significant financial resources and the use of a large number of energy-intensive equipment, and therefore have significant GHG emissions already at the initial stage of the life cycle of the OGI before the start of its operation.

During the construction of a pipeline system on site, carbon emissions are generated by the equipment used, powered by various energy sources (fossil fuel, electricity): cranes, excavators, trucks, DC welding machines, electrode drying cabinets, etc., and are calculated based on the carbon emission factors from energy sources, power consumption and the time spent operating the equipment according to formula (3).

According to the source [5], the carbon emission level for the construction of large public buildings is set at 800.15–1296.44 kg/m², and to assess emissions during the construction of industrial buildings, such as oil pumping stations, gas compressor stations, an average value of 1000 kg/m² is selected.

Stage IV. Operation of the OGI.

At this stage, the largest emissions are generated in the entire life cycle of the infrastructure. (In many cases, the production stage is also characterized by large emissions.) A large number of emissions are due to significant energy costs, without which it is impossible to operate the infrastructure.

At the stage of operation of the OGI, the main emissions are formed during the operation of energy-consuming equipment. GHG emissions from the gas pipeline system are supplemented by emissions from:

- organized leaks from the pipeline system arising as a result of technological operations;
- unorganized leaks from technological equipment through connections and seals;
- emissions during emergency situations.

According to paragraph 3.3 of the Order of the Ministry of Natural Resources and Environment of the Russian Federation dated May 27, 2022 No. 371 "On approval of methods for quantitative determination of greenhouse gas emissions and greenhouse gas absorption" [2], fugitive emissions and emergency emissions are *not included* in the quantitative determination of fugitive greenhouse gas emissions in organizations.

In GI, the gas pumping units (GPU) installed at GCS are the main consumers of natural gas and sources of GHG emissions. The capacity of the GPU ranges from 6 to 25 MW, and from 1 to 10 GPUs, including backup ones, can be installed at each GCS. More than 80 % of the gas consumed for its own process needs during gas transportation is spent on fuel needs of the GPU.

GHG emissions generated during compressor operation are equal to

$$CF_{\text{comp.}} = \sum_{i=1}^{n} w_i EF_e t_i \,, \tag{4}$$

where w_i is the operating capacity of the i-th GPU; EF_e is the coefficient of conversion of electrical energy into CO_2 emissions; t_i is the operating time of the i-th GPU; n is the number of all operating GPU.

Carbon emissions increase with the increase in pipeline capacity due to the increase in energy consumption. During operation of the linear section of the main gas pipeline, fugitive emissions are also formed during repair work and maintenance, when technologically justified operations are carried out with the release of natural gas into the atmosphere. The quantitative determination of fugitive emissions of CO_2 and CH_4 for a time period t is carried out by a calculation method based on data on the consumption of the hydrocarbon mixture for the implementation of technological operations or the volume of their removal (bleeding, dispersion) without combustion or catalytic oxidation. The calculation is performed according to the formula [2, pp. 3.5, 3.6]

$$CF_{\text{fug.}i} = \sum_{j=1}^{n} \left(FC_j \cdot W_{i,j} \cdot \rho_i \cdot 10^{-2} \right), \quad (5)$$

where $CF_{\text{fug.}i}$ is the fugitive emissions of the i-th greenhouse gas for the period t, ton; FC_j is the consumption of the j-th hydrocarbon mixture for technological operations (volume of removal without combustion) for period t, thousand m^3; $W_{i,j}$ is the content of the i-th greenhouse gas in the j-th hydrocarbon mixture for period t, vol. %.; ρ_i is the density of the i-th greenhouse gas, kg/m^3; i is the CO_2, CH_4; j is the type of hydrocarbon mixture; n is the number of types of hydrocarbon mixtures used in technological operations (discharged without combustion).

The consumption of hydrocarbon mixture for process operations and the volume of hydrocarbon mixtures removed without combustion (FC_j) are determined based on actual instrumental or calculated data for the reporting period.

Stage V. Dismantling, transportation from the site, processing/utilization.

The dismantling process is similar to the construction process, but in reverse order, due to which carbon emissions at this stage can be considered similar to those at the construction stage. To them are added GHG emissions generated during the processing or utilization of infrastructure components at processing plants. The calculation of the CF at this stage is made using formula (3).

I. Compensation measures for CF infrastructure

Carbon footprint compensation measures for OGIs may include:

1) purchasing emission quotas from other oil and gas transportation companies that have been able to reduce their emissions below established limits;

2) investing in emission reduction projects (e.g., renewable energy sources) or offset projects (afforestation);

3) purchasing certificates from specialized organizations that finance GHG emission reduction projects.

IV. Carbon footprint of an accident or emergency

It should be noted that currently the calculation of the CF in the event of an accident of the OGI pumping hydrocarbons is not performed, which is a serious omission, since it does not allow for the accounting of a significant portion of emissions that affect climate change. In the event of an accident, the size of the leaks is determined and the damage is assessed, including the amount of

GHG emissions.

In order to prevent malfunctions of oil and gas pipelines and emergency situations, their regular diagnostics and inspections are carried out to detect and assess deformations, welding defects, dents, damage to pipeline protection, as well as possible leaks of natural gas. Monitoring of operational parameters (pressure, temperature) of pipelines and pressure vessels is also carried out.

The main reason for the cumulative growth of the carbon footprint of the gas condensate is the depressurization of its pipeline under pressure, accompanied by the release of gas condensate or crude oil. Possible causes (risk factors) of pipeline depressurization and design and technological measures to reduce the likelihood of these risks are presented in table 1 [6]. These measures, in essence, are passive or active preventive barriers that reduce the likelihood of the depressurization of the gas condensate.

Table 1: *Preventive barriers for oil and gas pipelines that reduce the likelihood of risks occurring and the severity of their consequences*

Risk factors	Preventive barriers
External corrosion	• Corrosion allowance calculated for a 30-year service life of the pipeline; • External anti-corrosion coating of the pipeline; • Cathodic protection calculated for a 30-year service life of the pipeline; • Conducting an inspection to determine the thickness of the pipeline and the presence of defects caused by corrosion.
Internal corrosion	• Corrosion allowance calculated for a 30-year pipeline service life; • Internal protective coating of the pipeline; • Conducting an inspection to determine the thickness of the pipeline and the presence of defects caused by corrosion.
Mechanical damage	• Protection of the pipeline with a protective casing; • Monitoring of vessels passing the area of the laid pipeline, as well as marking the location of the underwater pipeline on the navigation chart; • Permission to carry out any operations near the pipeline.
Earthquake	• Design of a pipeline capable of withstanding the maximum seismic activity recorded in the area for the last 2,000 years; • Monitoring of seismic activity in the area of possible pipeline reach.
Ice impact (stamukhas, hummocks)	• Pipeline design capable of withstanding ice impacts throughout the entire service life; • Annual inspection of the pipeline to determine the impact of ice formations.
Internal erosion	• Anti-friction coating that provides protection for the internal steel surface of the pipeline; filtration of the transported product to remove as much erosive impurities as possible.
Exceeding the maximum permissible pressure level	• Pipeline design capable of withstanding increased pressure; • Control of the parameters of the transported product; • Training for operators servicing the pipeline; Strict control of all operations carried out with the pipeline; • Equipping the pipeline with a system of safety valves.

Risk factors	Preventive barriers
Operational errors, pigging, and restoration	• Pipeline design that ensures unimpeded passage of the projectile; • Work permit to perform an operation using intelligent pigs; • Performing operations by trained personnel.
Maintenance errors	• Conducting maintenance strictly according to the existing maintenance program; • Work permit to conduct relevant work of any maintenance; • Conducting maintenance by specially trained personnel.
Hidden defects of material and/or welds	• Assessment and quality control during pipeline construction; • Pressure testing of the pipeline before starting its operation; • Testing the pipeline using defect detection equipment.

None of these *preventive* barriers (or even all of them together) guarantees the OGI against depressurization, so in practice they are supplemented with *parry* barriers, which are designed to reduce the consequences of OGI depressurization [7]. As an example, Fig. 1 shows a "Bow-Tie" diagram (BTD) with *preventive* (left) and parry (right) barriers for the case of exposure to external and internal corrosion.

Figure 1. *Bow-Tie diagram for pipelines exposed to external and internal corrosion*

Note to Fig. 1: Preventive barriers: 1 – corrosion allowance calculated for a 30-year pipeline operation period; 2 – external anti-corrosion coating of the pipeline; 3 – cathodic protection, for a 30-year pipeline operation period; 4 – inspection to determine the pipeline thickness and the presence of defects caused by corrosion; 5 – corrosion allowance, for a 30-year pipeline operation period; 6 – internal protective coating of the pipeline; 7 – inspection to determine the pipeline thickness and the presence of defects caused by corrosion. Parrying barriers: 1 – leak detection system; 2 – emergency shutdown: pressure relief; 3 – fire warning and extinguishing system; 4 – leak elimination plan; 5 – accident elimination plan.

An emission from a gas pipeline may result in the formation of a cloud of fuel-air mixture (FAM) and its subsequent ignition, with the formation of a burning torch or a spill fire [8]. An emission of a multiphase hydrocarbon medium may cause serious damage to the environment and lead to the loss of production due to the blocking of the export channel during the period of eliminating the consequences [8].

In light of the Paris Agreement, the risk analysis procedures carried out at the design stage of the OGI should not only assess their safety level, but also provide an assessment of the project's CF. At the stage of risk-oriented operation of the OGI, it is necessary to plan and implement organizational and technical measures to minimize the CF, by ensuring high reliability of the OGI according to the criterion of its integrity.

V. Conclusions

- It is necessary to initiate a topic on assessing the magnitude of the emissions arising from leaks and accidents of the oil and gas industry, which do not currently fall under the Order of the Ministry of Natural Resources and Environment of the Russian Federation dated May 27, 2022 No. 371 [2].
- It is advisable to introduce mandatory certification of each oil and gas industry facility for its emissions. This passport must be confirmed annually. The presence of such passports will allow monitoring the country's emissions and the rate at which Russia's emissions approach zero emissions. To fill out the passport, it is necessary to conduct a regular analysis of GHG emissions throughout the entire life cycle of the OGI, with mandatory consideration of emergency emissions.
- The largest emissions in the life cycle of the OGI are generated at the stages of their operation and construction. With the growth of the length and throughput of the OGI, its emissions also increase.
- To reduce GHG emissions into the atmosphere, the use of energy-efficient technology and process equipment, the use of new generation gas pumping units with low-emission combustion chambers is becoming a priority.

Abstract

Growing global demand for energy and reducing environmental impacts create a need for energy-efficient technologies. Combined heat and power (CHP) is more efficient than traditional methods in terms of efficiency because it produces both electricity and thermal energy. In this paper, we review the current state of combined heat and power (CHP) technology, evaluate its performance in various applications, and discuss the importance and challenges of its wider use. Combined heat and power systems have both environmental and economic advantages. This is primarily due to their high efficiency. Today, it already reaches 60%, which is 82% of the theoretically possible level.

Keywords: energy efficiency, combined heat and power, cogeneration, sustainable energy, energy-saving technologies

I. Introduction

In the structure of world energy, the share of combined-cycle plants (CCP) producing electric and thermal energy is increasing. In this case, thermal energy is used for additional production of electric energy. A combined-cycle plant consists of two separate units: a steam power unit and a gas turbine unit. Both natural gas and petrochemical products, such as fuel oil or diesel fuel, can serve as fuel for a CCP.

Systems that simultaneously produce both heat and electricity are called combined heat and power systems or "cogeneration" systems. Combined heat and power systems are widely used in the paper, chemical, pulp and paper, and oil refining industries. These industries make maximum use of combined heat and power systems to meet the needs of the industry using both electrical and thermal energy. Most combined heat and power systems use steam turbines (Rankine cycle) and gas turbines (Brayton cycle) to produce electricity. In gas turbines, the working fluid is air, while in steam turbines, the working fluid is steam. Using waste heat in power production is economically advantageous.

Fig. 1 and 2 show idealized diagrams of thermal power plant systems with steam and gas turbines.gas turbines.

Power systems that only produce electricity dump large amounts of waste heat into low-temperature reservoirs such as rivers, oceans, and the atmosphere. Systems that only produce heat do not utilize the potential of high-temperature working fluids to create work. Thus, CHP systems attempt to utilize fossil fuels as much as possible.

Combined heat and power systems produce both electricity and heat using a single fuel source. This is also an indication of the high efficiency of combined heat and power systems, as they produce both heat and electricity without reusing fuel, thereby reducing greenhouse gas emissions and reducing waste to the environment.

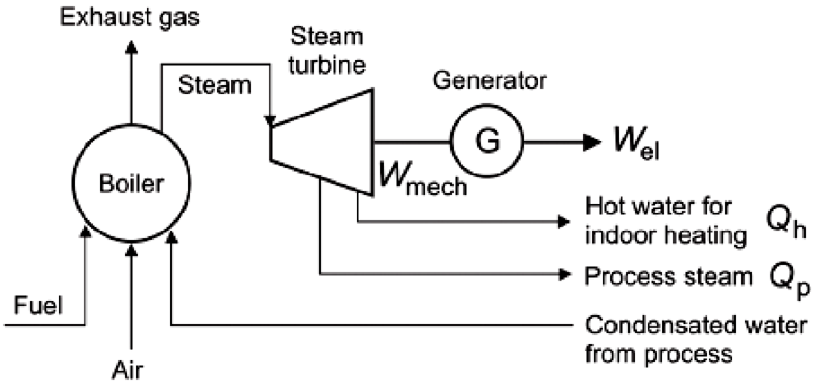

Figure 1: *Steam Turbine Combined Heat and Power System*

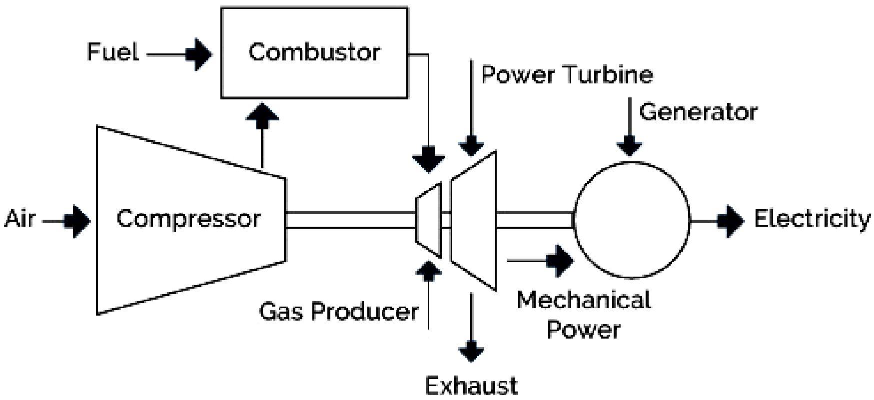

Figure 2: *Gas Turbine Combined Heat and Power System*

The concept of cogeneration was first used in the 19th century to produce industrial waste heat. Previously, this waste heat was used in industrial processes. Technological advances in the 20th century, as well as the development of turbine and engine technologies, have had a positive impact on the development of combined heat and power systems.

CHP technology has developed significantly in recent years. Advances in combustion engineering, materials science, and control systems have helped improve the efficiency and reliability of CHP.

CHP systems with different configurations such as gas turbines, steam turbines, and combustion engines have expanded the applications of CHP. The main results are that CHP reduces greenhouse gas emissions, increases efficiency, and saves energy or fuel, which reduces emissions to the environment.

In addition, research is focused on optimizing the integration of the CHP system with renewable energy sources. Combined cycle systems and fuel cells are also under development and are an ongoing topic of research.

II. Main configurations of the CHP system project

There are three main types of CHP plant configurations: a steam turbine design (Fig. 1), a gas turbine design (Fig. 2), and a combined cycle design that includes both a gas and steam turbine (Fig. 3).

A steam turbine is powered by high-pressure steam. This high-pressure steam is produced by a boiler or a heat recovery steam generator (HRSG). It differs from gas turbines in that it does not consume fuel directly. The fuel that powers the process is a fired boiler or plant equipment that produces heat for the HRSG.

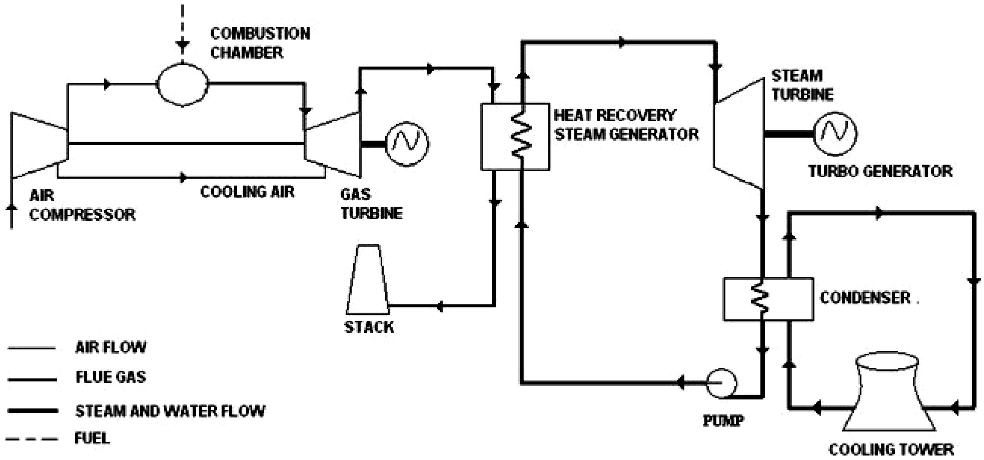

Figure 3: *Gas and Steam turbine design*

Steam turbines follow the Rankine cycle (see Fig. 1). This thermodynamic cycle involves pumping water at high pressure and heating it to produce high-pressure steam. Steam turbines convert the high-pressure steam into mechanical energy, which powers an electric generator. CHP systems use low-pressure steam from the steam turbine to meet on-site heating needs. The condensed liquid is returned to the pump and the process is repeated.

Gas turbines are open-cycle, constant-pressure heat engines. An application of the Brayton thermodynamic cycle. The gas turbine (see Fig. 4) compresses air and then mixes it with fuel. Combustion chamber. The combustor receives high-pressure fuel (200-400 psig) depending on the number of compressor stages and the compression ratio. If the fuel supply pressure at the field is insufficient, a gas compressor can be used to increase it. The combustor sends the hot gas to a turbine, which drives a mechanical shaft. The rotating shaft drives an electric generator and an air compressor.

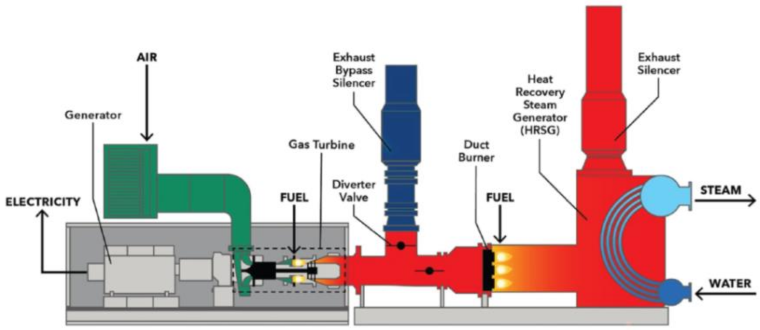

Figure 4: *Gas turbine design*

A combined cycle gas turbine (see Fig. 5) uses both a gas turbine and a steam turbine to generate electricity from the same fuel source, resulting in higher efficiencies than standard simple cycle plants. In a combined cycle plant, natural gas or other gaseous fuels are first burned in a combustion turbine to generate electricity.

After passing through the turbine, the hot exhaust gases retain useful energy that would otherwise be wasted. This residual heat is recovered by a heat recovery steam generator, which uses the thermal energy in the exhaust gases to boil water and generate steam.

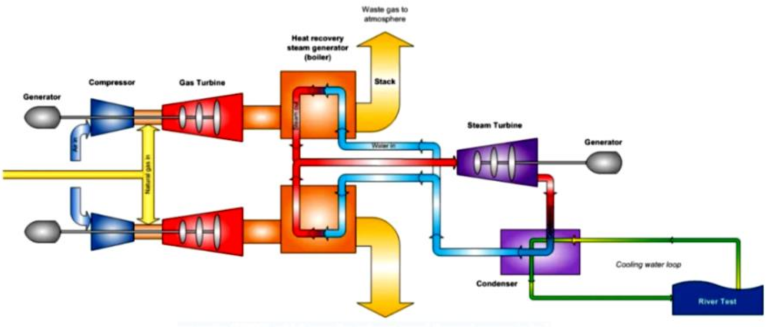

Figure 5: *Combine Cycle Gas Turbine Design*

III. Methods of calculation of system efficiency of heat and electricity production

CHP applications involve recovering heat that would otherwise be wasted in each application. Here's how CHP improves fuel efficiency.

The two metrics most commonly used to describe the efficiency of a CHP system are total system efficiency and net electrical efficiency.

The metric that compares the efficiency of a CHP system to its traditional counterparts (electricity supplied from the grid and useful heat generated in a local boiler) is called total system efficiency. Total system efficiency may be an appropriate performance metric for comparing the energy efficiency of a CHP system to traditional power sources on-site, if that's your goal.

Effective electrical efficiency is a metric used to compare electricity generated by power plants with electricity generated by cogeneration plants. If cogeneration power is to be compared with conventional electricity generation, the effective electrical efficiency metric is the correct choice. It is normal that one methodology does not fit all cases. Therefore, the methodology used must be chosen carefully and the results verified.

Overall System Efficiency

The overall system efficiency (ηo) of a CHP system is the net useful heating output (∑Q) and the sum of the net useful electrical output (W) divided by the total fuel energy input (Q), as shown below:

$$\eta_0 = \frac{W_0 + \sum Q_{TH}}{Q_{FUEL}}$$

Overall system efficiency is based on the fuel consumed and evaluates the combined outputs of the CHP plant (useful heat output and electricity).

CHP systems typically achieve overall system efficiencies of 65-70%.

Note that this methodology does not differentiate between electricity production and heat production. Thus, this methodology treats electricity and heat production as having equal value. In fact, electricity considered the more valuable type of energy due to its unique characteristics.

Effective Electrical Efficiency

Effective electrical efficiency compares the efficiency of combined heat and power systems to that of conventional power plants. The effective electrical efficiency calculation isolates the electrical output of a CHP system and takes into account the net heat output and fuel consumption.

The formula for calculating effective electrical efficiency is:

$$\mathcal{E}_{EE} = \frac{W_e}{Q_{FUEL} - \sum(Q_{TH}/\alpha)}$$

This metric is critical to comparing the efficiency of electricity generated by a CHP plant with electricity supplied from the grid, the primary source of electricity generation.

Effective electrical efficiency provides a clearer picture of the efficiency of electricity generated by CHP systems by calculating the thermal efficiency and the efficiency of conventional thermal generation.

Typical boiler efficiencies are 80% for natural gas boilers, 75% for biomass boilers, and 83% for coal boilers. Combustion turbine based CHP systems have an efficiency of 60-70%. Reciprocating engine based CHP systems have an efficiency of 70-85%.

IV. Advantages and disadvantages of combined cycle gas turbine plants

In the production of electricity, a combined cycle power plant is an assembly of heat engines that operate in tandem from the same heat source, converting it into mechanical energy to drive electric generators. The process begins with a gas turbine. In a gas turbine plant, the turbine is rotated by burning fuel (fuel oil, diesel fuel, natural gas). Natural gas enters the combustion chamber of the gas turbine, where it is burned, creating a stream of hot gas at high speed. The expansion of the hot gas flow through a series of turbine blades causes the turbine to rotate. The principle of operation is that in combined cycle plants, on the same shaft as the gas turbine is the first generator, which produces electric current due to the rotation of the rotor.

Then comes the stage of waste heat recovery. Passing through the gas turbine, the combustion products give it only part of their energy and at the exit from the turbine still have a high temperature (1300-1400°C). Then the combustion products enter the waste heat boiler (WHB), which is a series of heat exchangers that can transfer heat from the exhaust gases to water. There they heat the feed water and water vapor is formed. This reduces fuel consumption and increases the efficiency of the entire plant. The temperature of the combustion products is sufficient to bring the steam to the state necessary for the rotation of the steam turbine ($t=500^0$C and P=80 atm.). The second generator mechanically connected to the steam turbine.

Advantages of a combined cycle gas turbine plants

- *High efficiency.* Combined heat and power plants are known for their high thermal efficiency. By combining the steam and gas turbine circuits, this system is more efficient than traditional gas or steam turbine power plants because it uses a larger share of the energy contained in the fuel. Today, it already reaches 60%, which is 82% of the theoretically possible level. Previously, all the heat contained in the fuel that could not be converted into electricity was released into the environment, causing thermal pollution. The reduction in thermal emissions from a CCP compared to a steam power plant is exactly to the extent that the fuel consumption for electricity generation is lower. The use of a combined cycle reduces specific fuel consumption by approximately 6-12%.
- *Flexibility:* Combined cycle gas turbines operate efficiently at part load and provide stability during the growing but intermittent growth of renewable energy generation.
- *Low emissions.* Compared to other power plants, burning natural gas in a gas turbine results in lower emissions of pollutants and greenhouse gases, such as nitrogen oxides (NOx), sulfur dioxide (SO_2) and carbon dioxide (CO_2). The consumption of cooled water in a combined cycle plant is approximately three times less than in a steam power plant per unit of generated electricity. This is due to the fact that the capacity of the steam part of a combined cycle plant is 1/3 of the total capacity, and a gas turbine plant requires virtually no cooling water;
- *Fast start-up and load response.* The combined cycle gas turbine plant has high maneuverability, which is an important factor in ensuring the reliability of the power system, significantly easing the problem of covering the variable part of the electric load schedule. In addition, combined cycle gas turbine plants can function as power sources with both base and peak load. This means that they can operate continuously, providing a stable power base, and their ability to quickly increase capacity makes them valuable for meeting sudden surges in

demand;

- Combined-cycle power plants have a lower (approximately 40%) *specific cost of installed capacity*. This is due to the smaller volume of the construction part, the absence of a complex power boiler, an expensive chimney, a regenerative feed water heating system, the use of a simpler steam turbine and a technical water supply system, etc. CCP have a significantly shorter construction cycle. The main equipment of a CCP is delivered to the construction site in large modules, which allows for a significant reduction in installation time and provides the ability to introduce equipment in stages. It is much more profitable to build power plants with CCP than nuclear power plants;.
- *Significantly smaller construction cycle (9-12 months);*

Disadvantages of combined cycle gas turbine plants.

- *High temperatures mean high maintenance requirements*. Due to the high temperatures generated in a combined cycle power plant, care must be taken both at the design stage and during maintenance. The combustion chamber temperature can reach 1700°C, which is dangerous for the materials in the system and can reduce their service life.
- *Seasonal capacity limitations*. Seasonal capacity limitations are one of the disadvantages of combined cycle gas turbine plants, as combined cycle gas turbine plants are more efficient in the winter months due to heat recovery and the useful capacity is at its highest.

V. Practical use of a combined cycle gas plant

Currently, 3 combined cycle gas plants have been installed in Azerbaijan at the power plants of Azerenerji OJSC.

One of them is installed at the Sumgayit power plant with a capacity of 517 MW. According to experts' forecasts, the annual productivity of the Sumgayit Thermal Power Plant will be 3.8 billion kW/hours at a cost of 230 grams of fuel per 1 kW/hour of electricity. The demand for gas fuel will be 100 thousand m3 per hour or 630 million m3 per year. The general contractor for the construction of the power plant was Siemens.

At the Shimal State District Power Plant there is a combined cycle gas plant with a capacity of 400 MW, built by the Mitsui/Mitsubishi alliance. At the Shimal State District Power Plant (Shimal-2) there is another combined cycle gas plant with a capacity of 409 MW. Construction is carried out by the Japanese company Toyo Engineering Corporation.

According to Azerenergy estimates, due to the joint operation of the Shimal and Shimal-2 Combined cycle gas turbin units, the total volume of electricity generated by the power plant will be 5.7 billion kWh per year.

Currently, modernization work is ongoing at Azerbaijan's largest power plant, resulting in the construction of a combined gas turbine facility with a capacity of 1800 MW and its integration into the energy system.

The difference between the combined gas turbine station and the previous station is that while 335 grams of fuel used for 1 kW of energy in the previous station, this number will decrease by 110 grams to 225 grams in the new station.

As a result, the amount of waste released to the environment will decrease and 1.2 billion m3 of natural gas will be saved annually, and if the price of natural gas in Azerbaijan is taken into account, 200 million AZN financial funds will be saved annually. The efficiency of the station will increase between 22 percent and 60 percent.

Compared to steam power of the same capacity, the difference between combined heat and power plants is that the combined cycle gas turbin unit uses about three times less cooling water.

Today, the use of combined cycle gas turbines is a factor in energy security and welfare of the state.

VI. Conclusion

1. Combined Heat and Power systems increase efficiency by simultaneously producing both electricity and heat using a single fuel source. This not only reduces fuel consumption, but also reduces greenhouse gas emissions and waste to the environment.
2. Combined Heat and Power systems are more efficient than other conventional plants in different configurations. Brayton cycle gas turbine systems and Rankine cycle steam turbine Combined Heat and Power systems are economically and environmentally more efficient than other conventional plants.
3. The combined cycle gas turbine design, which combines both gas and steam turbines, is the most efficient in terms of efficiency, with efficiencies as high as 70%. Despite the disadvantages of temperature and seasonal power limitations, the benefits of combined cycle gas turbin are high.
4. The practical application of combined cycle gas turbin systems in Azerbaijan's power plants emphasizes their role in increasing the energy efficiency and sustainability of the country. The modernization and integration of new combined cycle gas turbin units is expected to significantly reduce fuel consumption and environmental impact, saving significant financial resources each year.

Abstract

According to the normative document, the comparison of the calculation results of explosion pressure of the gas-air mixture in the room carried out in the work showed that the obtained result does not correspond to the established limit. This fact testifies to the unsuitability of the developed calculation methods. When determining the explosion pressure, it is necessary to use the explosion power hypothesis instead of HWS (hot water supply) energy hypothesis. The results of the calculation of the explosion parameters of the gas-air mixture based on the energy hypothesis using the concept of "TNT equivalent" do not correspond to the results of experimental studies.

This fact indicates the unsuitability of the calculation methods developed and approved in accordance with "the established procedure". The calculation results obtained according to the approved methods mislead consumers.

Keywords: gas-air mixture, explosion pressure, overpressure, fire hazard, hazard factor, probability

I. Introduction

In order to determine explosion hazard categories in the room, the indicator of "explosion overpressure" is used. If the overpressure exceeds 5 kPa, premises are classified as explosion and fire hazardous place. To determine the overpressure equation [1] is used:

$$\Delta P = 100(P_{max} - P_0)mZ/(V_{ac}\rho C_{st}K_l) \qquad (1)$$

where: P_{max} – maximum explosion pressure, which cannot be greater than 900 kPa; P_0 – initial pressure equal to 101 kPa; m – mass of combustible gas in kg; Z – coefficient of participation of combustible gas in the explosion, for methane Z = 0,5; V_{ac} – available room capacity, м^3; ρ – gas density kg/m^3; C_{st} – stoichiometric concentration of GG by % (volume), for methane C_{st} = 9,35 %; K_l – coefficient that takes into account the leakiness of the room, K_l = 3.

The amount of gas entering the room is determined on the basis of the following assumptions:

- The most unfavorable variant of the accident or period of operation in which the largest number of GG (gas generators) are involved in the explosion is selected as the calculated one;
- The entire contents of the apparatus enter the room;
- Gas leaks simultaneously from the pipelines supplying the apparatus through the forward and reverse flow during the time required to shut down the pipelines;
- Liquid evaporates from the container, from the liquid spillage surface and from freshly painted surfaces.

For an example of implementation of the described methodology, let us determine the explosion pressure in the room with a volume of 80 m^3, in which there is a block of 1 m^3, operating at a methane pressure of 4 MPa. At complete depressurization of the block, 40 m^3 of gas from the block and 60 m^3 of gas enters the room through the direct and return flows feeding the block. The total gas flow into the room reaches 100 m^3. The density of methane is 0,714 kg/m^3.

Substituting the data into the above equation gives an overpressure value in the room equal to 1850 kPa.

Comparing the obtained value of overpressure with the limit value of 900 kPa, we notice that the obtained result does not correspond to the established limit. A deeper analysis of the situation revealed another inconsistency of the explosion process with the physics of the phenomenon in question: gas exploded in the room in the absence of oxygen in the air, so the volume of gas entering the room was greater than the volume of the room.

II. Methods

What will be the excess pressure in case of gas explosion in the room?

To answer this question, it is sufficient to determine the volume of gas in the room corresponding to the stoichiometric composition of the gas-air mixture. For methane, the stoichiometric gas concentration is 9,35 %. If the capacity of the room is 80 m^3, the volume of gas involved in the explosion will be about 7,5 m^3, its mass is m = $V_{ac}\,\rho C_{st}/100$. If we substitute this mass of gas into the equation, the equation is reduced to the following form.

$$\Delta P = (P_{max} - P_0)Z/K_l \quad (2)$$

The overpressure in the room in an explosion of a stoichiometric gas-air mixture is 133 kPa.

The fire hazard category of the room after the explosion pressure adjusting remains unchanged (A), however, if it is necessary to determine the value of the impact zone radius, the result will be significantly different from the value obtained according to the NPB methodology.

According to the thermodynamics of gas oxidation process during a cloud explosion in an open space, the overpressure cannot be higher than 900 kPa. However, the format of the equation presented in the NBP allows any flow pressure not limited by this limit to be plotted. Due to the inconsistency of the presented equation with the physical meaning of the process at cloud explosion, for calculation of cloud explosion parameters we use the methodology of PB 09-540-03[2], as well as the data of W. Marshall [3] and S.I. Taubkin [4]. In accordance with this methodology, the overpressure of the explosion is determined depending on the TNT equivalent mass of the gas involved in the explosion and the dimensionless coefficient K, taken in accordance with Table 1.

Table 1: *Classification of destruction zones*

Class of destruction zones	Coefficient K	ΔP, кПа
0	1	500-800
1	3,8	100
2	5,6	70
3	9,6	28
4	28	14
5	56	2

The radius of the destruction zone is determined by the expression

$$R = K(W_т)^{0,333}/(1 + (3180/W_т)^2)^{0,167} \quad (3)$$

The TNT equivalent value W_T for a gas-air mixture is determined by the equation

$$W_т = 0,4\dot{q}zm/0,9/q_т \quad (4)$$

where

0,4 is the coefficient that takes into account the share of the explosion energy of the gas-air medium spent directly on the formation of the shock wave;

0,9 - fraction of TNT explosion energy spent directly on shock wave formation;

q` – specific heat of combustion of gas, kJ/kg;

q_T – specific energy of TNT explosion, equal to 4520 kJ/kg;

z – fraction of the gas mass involved in the explosion;

m – mass of gas in the gas-air mixture cloud, kg.

To determine the cloud explosion overpressure beyond the limits set by the table (at ΔP>100 kPa and ΔP<2 kPa), we use the dependence ΔP = f(K) in the following form

$$\Delta P = P_{max}/(1 + K^3)^{0,5} \quad (5)$$

where, P_{max} is the maximum explosion pressure of gas-air mixture, kPa.

In accordance with the instructions of NPB - 105-03 it is allowed to take the value ΔP_{max} = 900 kPa. According to the data of Taubkin S.I. [4], the specified value of the maximum overpressure at explosion of methane-air mixture is 606 kPa. Using the equation [5] at any value of the coefficient K the overpressure is within the established limitation of its maximum value.

In the work of Marshall B [3] we find an indication that the fatal injury of people in an explosion is realized in different conditions in different ways. A person in an open area may be affected by an air shock wave with an overpressure of 500-800 kPa. In buildings and premises a pressure of 100 kPa is sufficient for this purpose. It is found that in buildings and premises a person dies not from the pressure of the explosion, but from fragments of building structures.

The conditional probability of human injury in accordance with the guidelines of NPB 105-03 and SP 12.13130.2009 is determined by the value of the probit function.

$$Pr = 5 - 0{,}26 \ln V \quad (6)$$

Where, V – hazard factor determined by the equation

$$V = (17{,}5/\Delta P)^{8,4} + (290/i)^{9,3} \quad (7)$$

Here ΔP - is the overpressure of the explosion, kPa; i - is the impulse of the pressure wave, Pa/s.

To check the correctness of the conclusions of methodological and normative documents, let us perform a control calculation, the purpose of which is to determine whether the overpressure leading to fatal human injury (100 kPa) corresponds to the conditional probability of human injury equal to 100 %. As an example, we selected a cloud of methane-air mixture in which 500 nm^3 of gas is distributed. The calculation results are presented in Table 2.

As follows from the analysis of the calculation results, an overpressure of 100 kPa corresponds to a conditional probability of injury to people equal to 81 %. The conditional probability of 100 % corresponds to an overpressure of about 500 kPa. Obviously, the equation of the Probit-function presented in the normative documents corresponds to the scenario of ESW (explosive shock wave) impact on a person located at the outdoor site.

In order to determine the ECD in the room, the equation of the probit function must be transformed to the following form:

$$Pr = 7{,}4 - 0{,}25 \ln V \quad (8)$$

The results of the calculation are presented in Table 3.

The change of dependence for the probit-function provided convergence of the result of the explosion wave impact on a person in the room, the conditional probability of his injury is equal to 100 % at the pressure of ESW of 100 kPa.

IV. Discussions and Results

The results of the calculation of the explosion parameters of the gas-air mixture based on the energy hypothesis using the concept of "TNT equivalent" do not correspond to the results of experimental studies.

This fact indicates the unsuitability of the calculation methods developed and approved in accordance with "the established procedure". The calculation results obtained according to the approved methods mislead consumers.

Abstract

A review of existing methods for assigning and regulating operating modes for groups of wells shows that they do not always allow to obtain satisfactory results, since the complexity and unpredictability of the behavior of the reservoir system and the supply system require approaches that would take into account the uncertainty of conditions.
In this article, when assigning injection modes, a probabilistic decision-making and a decision-making problem are used under conditions of uncertainty for a group of 15 possible wells of the VII formation of the considered field.
The choice of a rational injection strategy under risk conditions is made based on the following considerations: the known probabilities of each strategy result determine the mathematical expectation of each strategy utility. The injection strategy maximizing the expectation of utility is chosen.

Keywords: gas lift wells, working agent consumption, well operation mode, decision making, strategy, risk conditions, uncertainty conditions, matrix

I. Introduction

When controlling the processes of gas lift oil production, the main control parameter is the consumption of the working agent. In this regard, the problem of its rational distribution arises. Usually, the volume of compressed gas is limited, so the task is to distribute it over a group of wells in such a way as to ensure its total consumption minimum.

In practice, there are various methods of assigning operating modes for groups of gas-lift wells [1-5].

A method for operating a group of gas-lift wells, based on increasing for conditions of limited resources of the working agent the working agent consumption in wells with a maximum increase in flow rate is known [6]. An equal amount of gas is pumped into all wells, then the flow rate is measured for each well and the same increment of gas flow is set. After that, the flow rate is measured again, the wells are ranked in descending order of the increase in flow rates. Subsequently, the resources are distributed in such a way that at first the gas flow rate increase in the well is set with the maximum production increment (in the first well) until this increment becomes equal to that measured earlier in the second well. The process is carried out in a number of wells until all gas resources are exhausted. To improve the accuracy of the calculation, after the exhausting gas resources for each well, its flow rate is reduced by the same amount, the oil flow rate is measured for each well and the gas flow rate in the wells with a maximum decrease in flow rate is increased.

In [7], methods for assigning operating modes for groups of gas-lift wells producing non-Newtonian oils are studied.

Work [8] proposes a technique for choosing a certain "compromise" solution for a group of gas-lift wells. The mode is called "compromise" because it is not the best for all wells, however, extending it to a group makes it possible to achieve a total gain in the amount of fluid produced while reducing the flow rate of the injected agent. The choice of the mode was carried out using the apparatus of fuzzy sets theory [9, 10]. With this approach, the lack of information about the processes was modeled by a "fuzzy" (vague) formulation of goals and restrictions imposed on the functioning of the considered group of wells. In addition, the choice of mode was implemented based on the use of a generalized desirability function.

However, the above methods do not always allow to obtain satisfactory results, since the complexity and unpredictability of the behavior of the reservoir system and the supply system require approaches that would take into account the uncertainty of conditions.

Decision making theory, as one of the fundamental sections of the theory of operations research, is precisely aimed at solving such problems.

The content of the decision-making task is to determine the best or acceptable course of action to achieve one or more goals. It is obvious that the application of a scientific approach to the decision-making problem will contribute to the optimization of all management functions and thereby increase their efficiency.

Any decision-making process includes the following elements:

- Target. The need for decision-making is determined by the goal or several goals to be achieved;
- Alternative solutions - different options for achieving goals;
- External environment - the totality of all external factors affecting the outcome of the decision;
- Outcomes of the decision;
- Decision selection rules (decision rules). These rules make it possible to determine the most preferable solution in the sense of the chosen criterion.

In the considered problem of regulating the processes of gas-lift oil production, the goal of making a decision is to minimize the consumption of compressed gas, an alternative is the choice of an injection strategy, due to the choice of a decision-making criterion, the external environment is a combination of various factors affecting the state of the reservoir-well system, the outcome is obtaining a real economy of the injected working agent.

Decision making theory uses various procedures to formalize preferences, that is, to express them in a single quantitative measure. The basis for them is the utility theory [11, 12].

Depending on the conditions of the environment and the degree of awareness, there is the following classification of decision-making problems: deterministic tasks or tasks under conditions of certainty, probabilistic tasks or tasks under risk, tasks under uncertainty [13, 14].

Decision-making under certainty conditions is characterized by an unambiguous or deterministic relationship between decision-making and its outcome. In this direction, decision-making theory is considered from the position of mathematical programming: linear, non-linear, dynamic [11, 12]. These tasks include resource allocation, inventory management, and transport tasks. The application of mathematical programming methods requires the availability of complete and reliable information in the form of a deterministic mathematical model and the need for initial data. Under these conditions, the problem situation is completely defined and there is no need to further define it with a hypothetical situation. This means that all priori probabilities of situations are equal to zero, except for one, which is equal to one. Equality to unity of the probability of a certain situation means that this situation is the only reliable one. Goals under certainty conditions are formally defined and expressed as an objective function and constraints. Preferences are expressed as explicit preference functions. The selection criterion is also known in an explicit formal form. The presence of the above information allows us to build a fully formalized model of the decision-making problem and find the optimal solution.

II. Methods

Decision making under risk. This problem arises when each adopted strategy X_i is associated with a whole set of possible outcomes $O_1, O_2, \ldots, O_m$ with known probabilities $P(O_j/X_i)$. The solution is found using the theory of statistical decisions [16, 17]. Considering random events and processes the incompleteness and unreliability of information in real problems is taken into account in this theory. The description of regularities and behavior of these random objects is made with the help of probabilistic characteristics. The probabilistic characteristics themselves are no longer random, so formal optimization methods can be applied to find the best solution. In this regard, the problems considered in the theory of statistical decisions belong to a particular class of decision making problems under certainty probabilities or decision making under risk.

Formally, the problem model can be represented as a matrix the elements of which l_{ij} are the utilities of the result O_j when using the solution X_i (Table 1). Let conditional probabilities be $P(O_j/X_i)$, j = 1, m; I=1, n

Enter the expected utility for each strategy is entered:

$$E\{u(x_i)\} = \sum_{j=1}^{m} u(O_j, x_i) P(O_j/x_i); \quad i = 1, \ldots n \tag{1}$$

Table 1: *The usefulness of the result Oj when using the solution Xi*

$X_i \backslash O_j$	O_1	O_2	…………………	O_m
X_1	L_{11}	L_{12}	…………………	L_{1m}
X_2	L_{21}	L_{22}	…………………	L_{2m}
. . . . . .				
X_n	L_{n1}	L_{n2}	…………………	L_{nm}

The decision rules for determining the optimal strategy X_i are written as follows:

$$E\{u(x_i)\} = \max_{x_k} E\{u(x_k)\} \tag{2}$$

Choice of decisions under uncertainty conditions [13, 15]. These tasks are characterized by great incompleteness and unreliability of information, typical for gas lift oil production processes. The theory of decision making under uncertainty differs in that a large uncertainty of information does not allow to build a strictly formal scheme for finding the optimal solution. The theory presents only methods for narrowing the set of feasible solutions depending on the information uncertainty degree. One of the determining factors here is the external environment (or nature), which may be in one of the unknown states.

Then the mathematical model of the problem under uncertainty is formulated as follows.

There is some matrix with dimensions m×n (Table 1). The elements of this matrix l_{ij} can be considered as the utility of the result O_j when using strategy X_i.

$l_{ij} = (O_j, X_i)$, $j=1,\ldots, m$; $i=1,\ldots, n$.

Depending on the state of the environment, the result O_j is achieved with probability $P(O_j/X_i,S_k)$.

In addition, the observer does not know the probability distribution $P(S_k)$. Regarding the state of the environment, certain hypotheses can be made. The assumptions about the probabilistic state of the environment are called subjective probabilities $P'(S_k)$, k=1,…K.

If the observer known the value of $P(S_k)$ then we would have a problem of decision making under risk. In fact, the state of the environment is unknown and the probability distribution $P(S_k)$ is also unknown.

The decision is made on the basis of the selection criterion. Selection criteria allows to define a rule by which it is possible to get one optimal solution or narrow the initial set of solutions if there is a lack of information. In any problem, the choice of a solution is assumed. that the set of states of nature $S_1, S_2,…,S_n$ implies a complete system of incompatible phenomena, which is directly related to the given task and at the same time is unknown to the person making the decision.

For each of the criteria set out below, it is assumed that a problem of choosing a solution under uncertainty with actions (strategies) $A_1, A_2,…, A_m$, environmental states $S_1, S_2,…,S_n$, and utility payments u_{ij}; i=1,…,m; j=1,…, n is given.

The main decision-making criteria under conditions of uncertainty are:

- Maximum Wald criterion;
- Savage's minimax risk criterion;
- Criterion of insufficient reason of Laplace;
- Criteria for the indicator of pessimism - Hurwitz's optimism.

The application of these decision-making criteria is considered when choosing the operation modes of a group of gas-lift wells.

Deterministic and indeterminate tasks can be considered extreme cases, such as complete knowledge or complete ignorance of the results of the injection strategy.

Due to its complexity and the interconnectedness of individual wells, deterministic tasks rarely occur or are completely absent in the operation conditions of a group of gas-lift wells.

III. Results

The measurements data of fluid flow rate and compressed gas consumption of 15 gas-lift wells of the VII formation of the considered field for the period 2005-2009 were taken into account.

To assign the injection mode for the entire group of wells as a whole, we apply the above problem with risk (probabilistic problem).

For this purpose, it is convenient to represent problem situations in the form of a matrix, in which each column determines the possible result of obtaining extractions in the liquid Q_j (m^3/day), and each row determines the possible strategy for injecting compressed gas V_j (thousand m^3). The elements of this matrix $l_{ij}=u(O_j,V_i)$ determine the possible results of obtaining selections from these 15 wells (Table 2).

Table 2: *The utility of the result Qj obtained when using the strategy Vj*

V_j		Q_j		
		$Q_1 \le 50$	Q_2 50÷100	$Q_3 > 100$
V_1	2,3	24	72	121
V_2	2,8	20	76	121
V_3	3,5	46	88	123
V_4	4,0	40	83	121
V_5	4,5	38	82	125
V_6	4,7	32	81	121
V_7	5,0	40	85	126
V_8	5,5	34	87	126
V_9	6,2	40	87	127
V_{10}	6,6	38	85	121
V_{11}	7,0	40	82	115

Here l_{ji} is the utility of the result of obtaining Q_j when using the V_i strategy. The usefulness of the results is expressed as average selections.

Table 3 shows the frequency characteristics of obtaining results Q_j when choosing a strategy Vi.

Table 3: *The frequency response of obtaining the result Qj when choosing a strategy Vi*

V_j	Q_j		
	Q_1	Q_2	Q_3
V_1	2	4	3
V_2	1	6	2
V_3	1	8	4
V_4	2	8	4
V_5	3	9	3
V_6	1	7	5
V_7	1	7	4
V_8	1	9	3
V_9	2	6	2
V_{10}	1	6	3
V_{11}	1	4	3

Table 3 calculates the conditional probabilities

$$P(Q_j/V_i) = \frac{n_j}{N};\; j = 1,m; i = 1,n$$

where N is the total number of wells, N = 15.

The expected utility for each strategy is given

$$E\{u(V_i)\} = \sum_{j=1}^{m} u(O_j, V_i) P(O_j/V_i);\quad i = 1,n \tag{3}$$

Decision rules for determining the optimal strategy

$$E\{u(V_i)\} = \max_{V_k} E\{u(V_k)\} \tag{4}$$

We determine $P(Q_j/V_i)$ of the distribution probability (Table 4).

Table 4: *Conditional probabilities of the Qj distribution when choosing a strategy Vi*

V_j	$P(O_j/V_i)$		
	$P(O_1/V_i)$	$P(O_2/V_i)$	$P(O_3/V_i)$
V_1	0,13	0,27	0,20
V_2	0,07	0,40	0,13
V_3	0,07	0,53	0,27
V_4	0,13	0,53	0,27
V_5	0,20	0,60	0,20
V_6	0,07	0,47	0,33
V_7	0,07	0,47	0,27
V_8	0,07	0,60	0,20
V_9	0,13	0,40	0,13
V_{10}	0,07	0,40	0,20
V_{11}	0,07	0,27	0,20

The mathematical expectation of the utility of each strategy $Eu(V_i)$ is calculated:

$Eu(V_1)$ = 24x0,13+72x0,27+121x0,20 = 46,8;

$Eu(V_2)$ = 47,5; $Eu(V_3)$ = 83,1;

$Eu(V_4)$ = 81,9; $Eu(V_5)$ = 81,8;

$Eu(V_6)$ = 80,2; $Eu(V_7)$ =76,8;

$Eu(V_8)$ = 79,8 $Eu(V_9)$ =56,5;

$Eu(V_{10})$ = 60,9 $Eu(V_{11})$ =47,9

Obviously, it is rational to choose strategy V_3, since it maximizes the expectation of utility.

Based on the result obtained, injection mode V = 3,500 m^3 should be assigned for all wells in the group. Then for the group as a whole injection mode will be $\sum V$ = 52 500 m^3, which provides liquid withdrawal $\sum Q$ = 15 x Eu(V_3) = 1245 m^3/day. It should be noted that, in fact, the average combined gas flow rate is $\sum V_f \frac{\sum V}{N}$ = 71 000 m^3, and, accordingly, the liquid flow rate is $\sum Q_f = \frac{\sum q}{N}$ = 1226 m^3/day (V, q - respectively, the volumes of injection and withdrawal of fluid for individual wells).

Thus, by determining the injection strategy for a group of gas-lift wells as a whole, it is possible to reduce the consumption of the working agent up to 25% without loss in production.

IV. Discussion

The paper proposes the use of decision theory in conditions of incomplete information, when random factors have a significant impact on the processes occurring during gas lift oil production. In this regard, a methodology has been developed for selecting the operating mode for groups of interacting gas-lift wells based on the criteria of the decision making theory under risk conditions.

The performance of gas-lift wells is presented in the form of a matrix, each column of which determines the possible result of obtaining fluid withdrawals, and each row determines a possible strategy for injecting a working agent. Elements of the matrix determine the usefulness of the result of obtaining when using the strategy, expressed in the form of average values of selections.

The considered problem of regulating the processes of gas-lift oil production for the purpose of making decisions is minimizing the consumption of compressed gas by an alternative to an injection strategy choosing, due to the choice of a decision-making criterion by the external environment. The combination of various factors affecting the state of the reservoir-well system results in real savings in the working agent consumption.

For the group of gas-lift wells under consideration, an injection mode was proposed with a reduction in the working agent consumption up to 25%.

Thus, a decision-making algorithm under conditions of risk and uncertainty can be built on the basis of preliminary formation of options for decisions to be made, identification of risk events in each of them, and, factors of uncertainty, assessment of each of the alternatives according to the presented criteria, selection of the least risky and most acceptable option.

Abstract

As a quantitative measure of risk, an indicator was used simultaneously taking into account two characteristics of a landslide: 1) probability of landslide; 2) the amount of damage caused by the landslide. The probability of suffering damage from a landslide is defined as a conditional probability depending on the probability of the occurrence of an adverse event and the probability of suffering damage from a landslide caused by this event. A graphical methodology for comparing approaches for determining landslide risk parameters with and without protective measures was provided. The condition of combining the risks of various negative events was used for the assessing of integral risk magnitude. A formula was derived with known values of cost indicators for results and expenditures for determining the absolute value of the effect of implementing protective engineering measures to reduce risk at sites located in high landslide-prone territories. The measure of effectiveness was the relative indicator of accident or disaster risk reduction per unit cost of activities aimed at mitigating it.

Keywords: risk, landslide, methodology, probability, engineering measure

I. Introduction

Most of scientific studies describe the concept of "risk", along with the probability of the occurrence of an adverse event, also includes another characteristic associated with this event - the amount of damage caused. This leads to interpretation of a quantitative measure of risk as a mathematical expectation of damage determined on a set of possible adverse events (average risk values).

Assuming that the damage from the landslide is zero, no deformed and destroyed area is at risk. A similar situation occurs with zero probability of a landslide, although the possible damage from it would be enormous. The situation is perceived as dangerous, risky only in cases where the probability of a landslide and the possible damage from its occurrence are different from zero or are real in everyday understanding.

The study of problems of analysis and risk assessment of landslide processes is devoted to the work of I.T. Aitmatov, K.C. Kozhogulov and O.V. Nikolskaya [1, 2], I.O. Tikhvinsky [3], A.L. Ragozin [4], Kh.Kh.Einshtein and K.S. Karama [5], N. Jenny [6], G.P. Postoyeva [7], V.G. Tishina [8], R.I. Choudkhary and P. Felentje [9], K.Sh.Shaduntsa, S.I.Mathsia and E.V.Bezgulova [10, 11] and other researchers.

In a previously published article by the authors [12], a detailed analysis of the above works was carried out and it was revealed that the methodological approaches of various authors differ in originality. Simultaneously, a systematic approach is clearly observed in all studies. Depending on the specialization of various authors, the specifics of system approaches also change (geological engineering, geomechanical, geoecological, geotechnical and mixed), but in almost all cases, applied methods of probability theory are used to one degree or another.

As W. Morris notes [1], one of the main difficulties in management activities is the need to make decisions under conditions of uncertainty or with incomplete knowledge about the possible consequences of the actions taken.

The fundamentals of the science of managing complex systems are presented in the monographs of W. Morris [13], M. Starr [14], E.M. Khazen [15], B. Gurney [16], I.V. Prangishvili [17], S. Yang [18] and et al.

As noted by N.A. Makhutov and R.S. Akhmetkhanov [19], for optimal risk management, the systemic properties of objects and the systemic properties of risks should be taken into account. An analysis of international experience in the development and application of organizational and economic risk management mechanisms shows that there's a fairly large number of mechanisms aimed at reducing the level of risk [20, 21].

V.N. Burkov [22] studying mechanisms for managing the risk level, as is customary in the theory of active systems, believes, that the structure of ecological-economic system in which the mechanism operates is two-level. The top level is occupied by the control body. In addition, at the top level there may be one or more insurance organizations. The lower level of this system is occupied by objects whose activities pose a potential threat emergency.

II. Description of the developed methodology for determining the risk magnitude of a landslide on a landslide-prone slope

As a quantitative measure of risk, it's advisable to use an indicator that simultaneously takes into account two characteristics of a landslide: 1) the probability of a landslide; 2) the amount of damage caused by the landslide. Based on the above, the measure of slope landslide risk is the average landslide risk indicator, calculated according to the following formula:

$$R = \sum_{i=1}^{n} P_i X_i , \tag{1}$$

where P_i is the probability of damage from a landslide X_i as a result of one of the possible impacts on a landslide-prone slope; X_i – the amount of damage from a landslide, expressed in cost terms; R – quantitative measure of landslide risk (average landslide risk), expressed in the same indicators as damage; n is the number of possible damage options that can occur during various types of landslide phenomena on a landslide-prone slope.

Thus, for the purpose of determining the risk magnitude of landslide phenomena according to expression (1), it's necessary to have information expressing the correspondence of the values of P_i and X_i, i=1, 2, ..., n. In the simplest case, such information allows to determine the law of probability distribution in the space of damage from landslide phenomena.

Assuming a continuous dependence of the probability P_i on the values of damage from landslide x, we obtain

$$P_i = P(x), \tag{2}$$

and expression (1) can be presented in integral form:

$$R = \int_{-\infty}^{\infty} xP(x)dx \cdot \quad (3)$$

In general case, when damage from a landslide can occur as a result of various unfavorable and independent events (impacts on a landslide-prone slope), the average risk of a landslide occurrence (process) can be determined according to the following formula:

$$R = \sum_{i=1}^{n} \sum_{j=1}^{m} P_{ij} X_i , \quad (4)$$

where P_{ij} is damage probability of landslide X_i upon the an event occurrence (i.e. impact on a landslide-prone slope) of type j.

In the probability of receiving damage from a landslide, formula (4) is defined as a conditional probability according to the following product:

$$P_{ij} = P_j P_i (j), \quad (5)$$

where P_j is the occurrence probability of an adverse event of j type (negative impact on a landslide-prone slope), contributing to the development of a landslide, $P_i(j)$ – the probability of receiving damage from a landslide X_i with a negative impact on a landslide-prone slope of j type.

Provided that damage from various impacts on a landslide-prone slope is measured on the same scale (for example, in value terms), and taking into account formula (5), to determine the average risk of a landslide, the following formula can be used instead of expression (4):

$$R = \sum_{i=1}^{n} \sum_{j=1}^{m} P_j P_i (j) X_i . \quad (6)$$

Formula (6) represents, that P_i expresses the distribution law of probabilities of negative factors impact on a landslide-prone slope, and $P_i(j)$ – distribution laws of damage from landslides for each of such negative impacts on a landslide-prone slope.

Formulas (1) – (6) determine the average risk of a landslide on a landslide-prone slope, regardless of the activity of an object located on the slope and exposed to a landslide hazard. It's advisable to consider the system "structure + people + technology + biota" as an object on a landslide slope. In the general case, an object represented by a person (who builds, operates structures and controls technology and biota) can perform two types of activities.

1. An object located on a landslide-prone slope can take measures to prevent or reduce losses from an adverse event (this means protective engineering measures). In this case, the object itself does not affect the possibility of its manifestation. The risks of such events are called "pure risks". These measures are associated with certain costs. In this case, in the formula for the average risk of a landslide, it's necessary to link the probability of damage from a landslide $P_i(j)$ with the costs incurred to prevent (reduce) it. In this case, expression (6) will take the following form:

$$R = \sum_{i=1}^{n} \sum_{j=1}^{m} P_j P_i (j, z_j) X_i , \quad (7)$$

where $P_i (j, z_j)$ is the damage probability of a landslide X_i upon the occurrence of a negative impact of type j and protective engineering measures taken against the specified negative impact with costs z_j;

The differences in formula (6) on the one hand and (7) on the other can be illustrated by the graph presented in Fig. 1.

In Fig. 1, $P(x)$ means the distribution of losses during a slope landslide in the absence of protective engineering measures, $P[X(z)]$ is the corresponding probability when carrying out protective engineering measures.

$\Delta X = X - X(z)$ - reducing the damage amount from a landslide as a result of implementing protective engineering measures.

2. The facility may take an adventurous position in relation to the development or exploitation of a landslide-prone slope, consciously choosing a situation characterizing different probability of landslide(s) occurring on the specified slope. The facility may choose a more risky situation with a greater likelihood of damage, expecting to receive additional benefits (at the same time, the requirements of regulatory documents for the construction and operation of structures on landslide-prone slopes are partially or completely ignored). In most cases, the object relies on the concept of "may blow over." Often the object consciously tries to compensate for deliberate adventurism by insuring its investments.

The risks of this kind can be called "adventurous speculative risks." Taking into account the possibility of such a choice, the average risk of a landslide is determined on the basis of the following expression:

$$R = \sum_{i=1}^{n} \sum_{j=1}^{m} g_{ij}(V) P_j P_i(j) X_i, \tag{8}$$

where $g_{ij}(V)$ is the probability of an object choosing a situation characterized by the probability of a landslide P_i on a landslide-prone slope with a negative impact on the j-type slope.

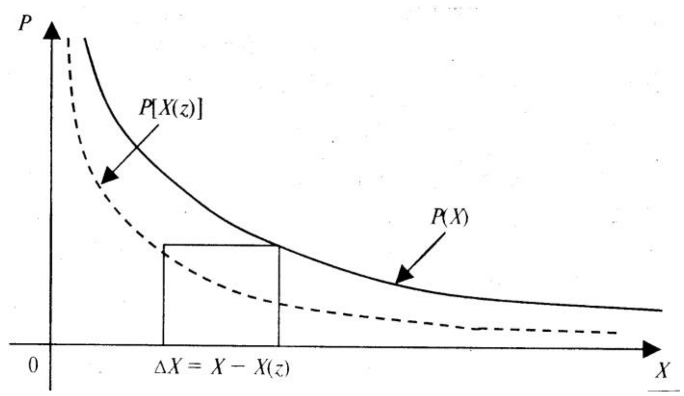

Figure 1: *Comparison of approaches for determination of the risk parameters of landslide manifestations when implementing and not implementing protective engineering measures on a landslide-prone slope*

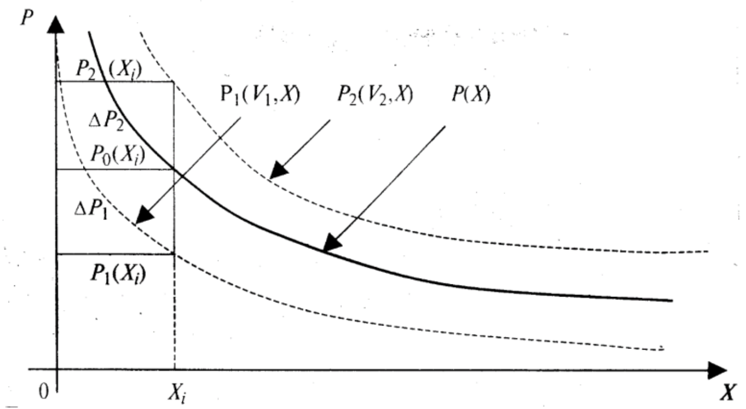

Figure 2: *Comparison of approaches for determination of the risk parameters of landslide manifestations on a landslide-prone slope in the initial state and during "adventurous" development*

The peculiarity of the approach for determining landslide risk on the basis of expression (8) can be illustrated by the graph presented in Fig. 2.

As is evident from Fig. 2, $P(X)$ means distribution law of damage from landslides in the initial state of a landslide-prone slope, $P_1(V)$ distribution law of damage from landslides in a more risky situation (adventurous approach).

As can be seen from Fig. 1 and 2, with different approaches to the development of landslide-prone slopes, it's possible to achieve various types of positive and negative risks of landslides.

III. Selection of risk management measures in high landslide-prone slope

Risk management at facilities located in high landslide risk zone is based on the developments of the general theory of risk analysis and that part of it relating to risk management [23]. In this regard, general principles and approaches are usually used when forming management decisions, the scientific justification of which is developed by the general risk theory.

It should be borne in mind that each of the listed approaches operates within the framework of a certain system of measures regulating management activities to reduce risk at facilities located in landslide-prone areas and the conditions for its implementation. According to their composition, they are divided as follows:

– regulatory measures representing the rights and obligations of parties, objects and other participants in the field of risk management;

– administrative measures related to the implementation of functions of control over the results and financial support of activities (if necessary, with enforcement of their implementation);

– economic measures involving economic stimulation of risk reduction activities at facilities located in high landslide hazard areas, the organization of its financial support, environmental and social interests of public development;

– technical measures determining the scope of possible technical solutions for reducing risk at facilities located in high landslide-prone areas, associated with the implementation of individual work aimed at protecting against the impact of the "field of damage and destruction" caused by a negative event, to reduce the potential damage and suchlike.

It should be noted that regulatory and administrative measures for risk management at facilities located in high landslide-prone areas with a generally form a set of restrictions, unconditional responsibilities for various participants in this activity, and limit the scope of their possible behavior in the socio-economic system. Effectiveness of risk management activities within this framework is determined by the correct choice of the system of permissible measures and the rational use of available economic and material resources in their implementation.

Economic results are taken into account in the vast majority of cases when developing territorial, engineering, technical and economic regulations and using administrative levers to regulate risk management at facilities located in high landslide-prone areas. If the regulatory framework and administrative framework interfere with the adoption of cost-effective decisions, as a rule, they are modified and changed as management experience accumulates.

However, in specific conditions, the management body, development of solutions in the field of risk management at facilities located in high landslide-prone areas, is always within the framework of certain legal, administrative and environmental restrictions, which it should not violate. Effectiveness of the decisions for reducing risk depends on the economic feasibility of the chosen system of management measures, taking into account these limitations.

The set of technical measures to influence risk at facilities located in high landslide-prone areas determines the space of possible solutions that can actually be implemented in each specific situation. Their composition is associated with the accessible level of scientific and technological development of society, since in market conditions the necessary equipment and technologies can be purchased practically without any restrictions, provided financial opportunities.

For the practice of risk analysis, the principle of integral hazard assessment is extremely important, according to which risk management at facilities located in high landslide-prone areas must comprehensively consider the entire range of events and the risks associated with them when developing management decisions. The fact is that negative events that cause damage and the damage themselves in real life can be interrelated.

From the point of view of theory and practice of risk assessment at facilities located in high landslide-prone areas, the simplest situation arises when considering the list of negative independent events. In this case, the integral risk R_{int} can be presented as a simple arithmetic sum of the risks from each negative event:

$$R_{\text{int}} = \sum_i R_i \ , \tag{9}$$

where R_i is the risk from the *i* negative event.

In the presence of interrelated risks at facilities located in high landslide-prone areas, expression (9) isn't suitable for assessing the magnitude of the integral risk. In certain situations this is due to risk absorption effects. Therefore, to assess the of the integral risk magnitude, you should use the formula for combining the risks of various negative events:

$$R_{\text{int}} = \bigcup_i R_i \ , \tag{10}$$

Where $\bigcup_i$ - represents the operation of combining sets.

In the case of non-overlapping risks at facilities located in high landslide-prone areas, expression (10) is equivalent to expression (9).

Note that the simplicity or complexity of the formula for assessing the integral risk at facilities located in high landslide-prone areas doesn't automatically transfer to management decisions. For example, expression (9) in no way means that managing the integral risk in each such case is reduced to a set of measures to manage each of them. It's due to the fact that risk reduction often measures at facilities located in high landslide-prone areas are aimed at blocking the main source of danger.

Taking into account the principle of integral hazard assessment when developing management measures to reduce risk at facilities located in high landslide-prone areas, in practice, can significantly complicate the solution of the problem, taking it beyond traditional optimization problems to maximum efficiency under given restrictions. As a result, in practical studies, control decisions can often be obtained on the basis of the methods, for example, simulation modeling.

It allows us to consider many different scenarios for the development of the consequences of negative events at facilities located in high landslide-prone areas, taking into account the likelihood of each, and compare them with each other in terms of consequences, complexity and effectiveness of using risk reduction methods for each of them. The most "rational" system of risk reduction measures is usually selected on the basis of such a comparison.

It should be noted that general approaches for determination of the effectiveness of any protective measures differ little in different types of life activities. All of them in one way or another involve comparison, comparison of results (*W*) achieved using the set of measures under consideration with the costs of them (*Z*).

With known values of cost indicators of results and costs, the absolute value of the effect from the introduction of protective engineering measures to reduce risk at facilities located in high landslide-prone areas may be determined according to the following formula:

$$E(Z,T) = W - Z = \sum_{t=1}^{T} \left(\sum_{i=1}^{k} W_{it} - \sum_{j-1}^{n} Z_{it} \right), \tag{11}$$

where *T* is the total operating time of the enterprise included in the project; W_{it} − result in the i direction in period *t*; Z_{jt} − costs in the *j* direction in period *t*.

Considering that the results of the implementation of protective measures in the case of pure risks manifest themselves in the form of a decrease in mathematical expectations of damage, expression (11) can be presented in the following form:

$$E(Z,T)=\sum_{t=1}^{T}\left\{\sum_{i=1}^{k}\left[\overline{X}_{it}-\overline{X}_{it}(Z)\right]-\sum_{j=1}^{n}Z_{jt}\right\}, \tag{12}$$

where $\overline{X}_{it}$ − is the average level of damage that occurred in period *t*, before the introduction of risk-reducing protective measures at the enterprise; $\overline{X}_{it}(Z)$ – the average level of damage determined after the implementation of risk-reducing protective measures at facilities located in areas with a high landslide hazard.
The index

$$\mathrm{I}(Z,T)=\sum_{t=1}^{T}\left(\sum_{i=1}^{k}\overline{X}_{it}+\sum_{j=1}^{n}Z_{jt}\right), \tag{13}$$

represents the total value of risk management costs at facilities located in high landslide-prone areas when implementing a set of control measures Z.
In the case of applying speculative risks at objects located in high landslide-prone areas, expression (11) for the assessment of the effectiveness of measures, the following relationship can be used:

$$E(Z,T)=\sum_{t=1}^{T}\left[\overline{\Pi}_t(Z)-\overline{\Pi}_t\right], \tag{14}$$

where $\overline{\Pi}_t(Z)$ is the expected average profit from an object located in high landslide-prone area in a year t if any protective measures *Z* are taken in relation to the risk, not necessarily related to its reduction; $\overline{\Pi}_t$ - expected average profit in the absence of these measures.

In general, the expected profit should be assessed taking into account the probability distribution of possible methods of operation of an object located in high landslide-prone area, the risk of losses from negative events and the costs of implementing risk management measures:

$$\overline{\Pi}_t=\overline{D}_t(Z)-R_t(Z)-\sum_{j=1}^{n}Z_{jt}, \tag{15}$$

where $\overline{D}_t(Z)$ is the expected amount of income in year *t*, when choosing a risk management strategy, is characterized by a set of costs $Z_{jt,}\ j=1,2,3,...,n;$ $R_t(Z)$ - the risk level at an object located in high landslide-prone area in year *t*, estimated by the expected average amount of damage.

Profit is determined in a similar way in the absence of measures *Z*. In a real situation, the indicators $\overline{\Pi}_t$ and $\overline{\Pi}_t(Z)$ can change places, for example, in cases where a more risky solution is deliberately chosen for an object located in high landslide-prone area in the hope of getting more profit by refusing from the implementation of known protective measures.

As a measure of efficiency, a relative indicator of reducing the risk of accidents or catastrophes at facilities located in areas with a high landslide hazard per unit cost of costs for measures to reduce it can be used:

$$E(R/Z)=\frac{R_1-R(Z)}{Z}=\frac{\sum_t R_{1t}-\sum_t R_t(Z)}{\sum_t Z_t}, \tag{16}$$

where R_1 is the risk indicator at the enterprise before the implementation of protective measures; $R(Z)$ - risk indicator at the enterprise after the implementation of protective measures; *Z* – cost of protective measures to reduce risk at the enterprise; $R_{1t}, R_t(Z), Z_t$ - values of the considered indicators in the period *t*.

Expression (16) is based on the indicators of both individual and social risk at a facility located in high landslide- and collapse-prone areas.

IV. CONCLUSION

By the authors for the first time as a quantitative measure of risk of a landslide, an indicator was used simultaneously taking into account two characteristics of a landslide: 1) probability of landslide; 2) the amount of damage caused by the landslide. It was revealed that the probability of suffering damage from a landslide is defined as a conditional probability depending on the probability of the occurrence of an adverse event and the probability of suffering damage from a landslide caused by this event. The authors have developed a graphical methodology for comparing approaches for determining landslide risk parameters with and without protective measures was provided. The condition of combining the risks a landslide by the authors of various negative events was used for the assessing of integral risk magnitude. The authors proposed the measure of effectiveness was the relative indicator of accident or disaster risk reduction per unit cost of activities aimed at mitigating it.

Absract

Geological risk belongs to the doubt and variableness of the reservoir characteristics and internal structure, like as porosity, permeability, heterogeneity, thickness, faults, crucks, and seals. These characteristics identify the amount and quality of the hydrocarbons in deposits, as well as the recovery coefficient and the production rate. Geological risk possible to reduce by acquiring and analyzing more data, like as seismic, well logs, core sampling, and producing history. In addition, by using suitable methods and models to assess the range of possible outcomes.

So, this paper discusses the results of studying terrigenous Mesozoic and Cenozoic rocks of the Sangachal-deniz-Duvanny-deniz-Khara-Zira oil and gas bearing region of the Baku archipelago element of the South Caspian depression as possible reservoirs of oil and gas, its characteristics and geological risk in changing of reservoir parameters [1].

To explain the nature of the change in rocks by depth, graphs of the dependence- dependence of porosity on depths were plotted.

The depth of occurrence of these rocks along the well sections varies from several hundred meters (Khara-Zira field) to 5500-6000 m (Sangachal-deniz, Duvanny-deniz fields). The wells uncovered rocks from the Quaternary to the middle Miocene (Chokrak). Well sections are represented by alternation of sands, sandstones, dolomites and clays. The wells completely uncovered the section of the Productive Series (PS). The maximum thickness of the PS in the Sangachal-deniz field and in the north-east part of Khara-Zira is 3950-4000 m. Hypsometrically elevated parts of the Sangachal-deniz and Duvanny-deniz structures, the thickness of the PT varies within 2960-3600 m. The minimum thickness of the PS was discovered by wells in the southwestern limb of the Sangachal-deniz uplift up to 3000 m.

The type of structure is brachianticline, which are associated fields. The arch part is fragmented by faults into blocks that these blocks are oil and gas-condensate. In the oil of the field, the amount of resin is 8-27%, asphaltene mass- 0.2-1.1%, paraffins- 6.0-20.1%. The content of light fractions, which have a boiling point of up to 300° C, varies between 31.4-40.0%, gasoline- 4.5%, naphtha- 12.1%. The hydrocarbon composition of oil is noted in the following order: methane- 52.1-66.8%, aromatic hydrocarbons- 12.2-21.5%, naphthenes- 12.3-35.1%. The density of reservoir oil ranges from 0.729 to 0.780 g/cm^3, and the density of degassed oil is 0.869-0.889 g/cm^3, condensate 0.759-0.797 g/cm^3.

The results of determining the porosity of samples taken from drilled wells were used, in addition, the density and permeability of rocks were studied by mechanical analysis of numerous samples. The porosity of the studied samples varies from 1.5 to 38%, the density in wet samples varies from 1.72 to 2.97 g/cm^3, and in dry samples from 1.72 to 2.97 g/cm^3, permeability - from 0 to 863·10^{-15} m^2. But at some depth, the permeability reaches 1910·10^{-15} m^2.

Keywords: porosity, permeability, mechanical analysis, section, clay, graphs of the dependence, sandy-silty rocks

I. Introduction

The Baku archipelago covers a large water area in the southwest part of the Caspian Sea [2, 3, 14, 18]. Ttectonically, it is the continuation of the South Gobustan and Lower Kura depressions toward the sea. Khara-Zira, Zanbil, Sangi-Mugan, Garasu, Gil, Kurdashi, Daşlı islands and many underwater salses such as Umid, Babek, Yanan Tava, Ateshgah, Mugan-deniz, etc. is known here that formed by the activity of mud volcanoes [11, 22]. Most of the deposits discovered here are related to mud volcanoes, for instance, Khara-Zira, Sangachal-deniz, Sangi-Mugan, Garasu, Duvanni-deniz, Kurdashi, Daşlı and etc. (Fig. 1).

The Sangachal-deniz-Duvanni-deniz-Khara-Zira island oil-gas-condensate field, which is related to the structures discovered in the northern part of the archipelago, is located 50 km southwest of the Baku city [3] (Fig. 2).

Since 1935, geophysical exploration (gravimetric, electrical exploration, aerial photoplanning, seismic exploration), structural and structural-prospecting drilling has been carried out in the field. Since 1951, the field deep exploration drilling have been involved. As a result of the conducted works, the geological structure of the field was studied, oil-gas-condensate horizons were discovered.

The oil content of the field was confirmed in 1963 by testing in well 24, drilled in the limb of the Duvanni-deniz structure. Here, primarily, an oil gush with a flow rate of 250 t/day was obtained from the VII horizon of the Productive series. In 1965, 150 t/day of oil was obtained from this horizon in the Sangachal-deniz structure, for this year, 300 000 m^3/day of gas was obtained from the VIII horizon in well 29 in the Duvanni-deniz field. İn 1974, 200 t/day of oil was obtained from the V horizon in well 361. Until 1995, 158 exploratory wells were drilled in the field, most of which are [3, 5].The oldest sediments are of middle Miocene age in the well section. The top of well sections are represented by Productive series, Absheron, Aghjagil and Quaternary [3].

This deposit as a whole was formed on the anticlinal belt created by local structures of Sangachal-deniz, Duvanni-deniz and Khare-Zira Island, complicated by the regional fault extending from the northwest to the southeast from the tectonic point of view. The studied deposit is represented by a single structure- brachyanticline, extending in the northwest-southeast direction along the VIII horizon and measuring 30x11 km. Transitional parts of local structures are manifested by densification of isohypses (Fig. 2).

The Sangachal-deniz local structure, which is separated from the Kanizadag structure by a long and shallow saddle, and from the Duvanni-deniz structure by a short and shallow saddle, has an asymmetric structure and a dome shape.

The Duvanni-deniz structure is complicated by a mud volcano. Its northeastern limb bend under the 45-50^0, and the southwest limb inclined under 35-40^0 dip angle.

The arch part of the Khara-Zira island structure is compounded by the mud volcano of the same name.

A longitudinal tectonic fault passes through the arch parts of the structures that make up the deposit as a whole. This fault is revers type in Sangachal-deniz area, and normal fault type in Duvanni-deniz area. This fault, which complicated the field, caused the northeast limb of the Sangachal-deniz structure to rise with an amplitude of 200-600 m, and the limb of the same name of the Duvanny-deniz structure to descend with an amplitude of 500-1400 m. The fault, which complicates the structures along its longitudinal axis, diverges into two tectonic faults with an amplitude varying from 30 to 150 m towards the southeast. As a result, the structure is divided into three parts: the northeast limb, the central part, and the southwest limb [3] (Fig. 2).

Figure 1: *Location scheme of fields and local uplifts of Baku archipelago*

II. Analysis of the problem

Porosity, as well as permeability, are considered to be one of the most significant indicators when determining the reservoir properties of terrigenous sedimentary rocks. The values of these properties are known to depend on a number of factors, such as the substantial and granulometric composition, the degree of sorting, the nature of the location of the clastic particles, the occurrence depth, the degree of compaction, the connection of pore spaces, the size of the particles, the structure and texture, and others.

The main components of the described rocks are sand, sandstone, siltstone, aleurolit, chlidolite and clay. The effect of specified rocks on the values of porosity and permeability is different depending on the size of the grains.

In accordance with this, during studying the relationship between reservoir properties and the composition of rocks, the following components were distinguished, which have different effects on the studied parameters.

- fraction of sand and coarse-grained siltstone, which is larger in the range of 0.1-0.01 mm. The presence of these fractions is favorable for reservoir properties [14].
- fraction of clay, medium- and fine-grained siltstone, fraction finer than 0.01 mm. They relatively weakly affect the values of porosity, but sharply reduce the permeability of reseroirs.
- the insoluble rock part, represented mainly by chlidolite. It reduces porosity and permeability.

III. Discussion of the problem

In the geological level of connections between porosity and permeability, there are opposite views. Some researchers argue that there is a direct dependence between them, and other researchers, on the contrary, deny this connection. It should be noted that the porosity and permeability of reservoir rocks depend on lithology, on the structure of the pore space, the depth of collection thicknesses and at the same time from cementing materials. To clarify the connections between these properties of rocks, it is necessary to take into account the composition of the latter. Thus, the cross section of the area under the study is mainly consists well-sorted sandstone-aleurolits, clayey-sandy, clayey-aleurolit-sandstones. Didn't consider some depth intervals they have high porosity and permeablity. However, in the depth intervals with low porosity and permeablity the percentage of cement materials is observed in the study area. Thus, by the large content of cement materials (over than 20%) the permeability don't dependence from porosity, while these rocks in most cases practically permeable due to secondary porosity, faults with less scale amplitudes, forming under the influence of over lying rock strata and compressing stresses [10].

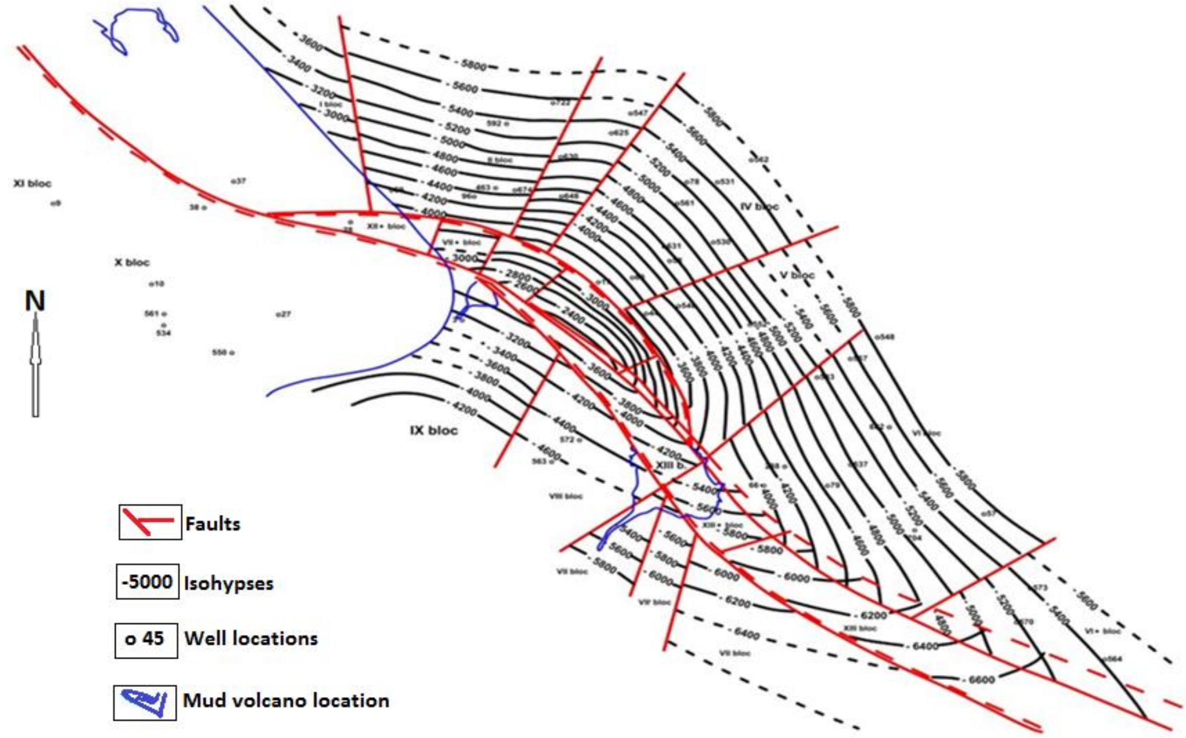

Figure 2: *Structure map of the Sangachal-deniz-Duvanni-deniz-Khara-Zira field*

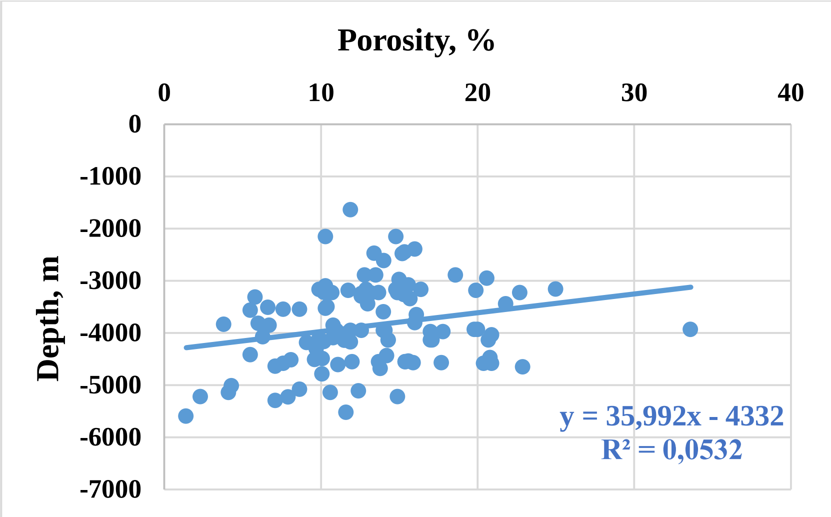
IV. Methods

One of the structures of the research area is Sangachal-deniz field. In the sections of wells drilled in this field, clayey-silty sandstones, clayey-silty sandy loams, clayey-sandy aleurolits and clayey aleurolits are distinguished by relatively high porosity [3, 17]. The porosity of these deposits varies within the range of 5.5-22.9%, 5.5-33.6%, 2.3-20.4%, 3.8-20.7%, respectively (Fig. 3).

With a higher content of clayey aleurolit particles, porosity decreases to 4-15% with the exception of depths of 3164 and 4140 m. At these depths, rock porosity is 22.9% and 20.7%, respectively. Apparently this is due to the compaction and fracturing of clayey rocks under the load of the overlying ones. Due to present a sufficient percentage of chlidolite by depth, the porosity is reduced to 5.5%, with the exception of rocks with a high degree of sorting of terrigenous material. Along the section from top to bottom, clayey-sandy subaleurolits with a porosity of 11-21% are observed with a higher content of the fraction finer than 0.01 mm in the range of 12.0-20.9%. The carbonate content of rocks varies between 2.3-15.0%, but there are exceptions. At a depth of 4302-4610 m, the carbonate content of chlidolites and aleurolit-clayey sandy loams is expected to increase, reaching values of up to 33.4-35.8%. Such a situation could not affect the porosity and permeability of rocks; they are almost impermeable.



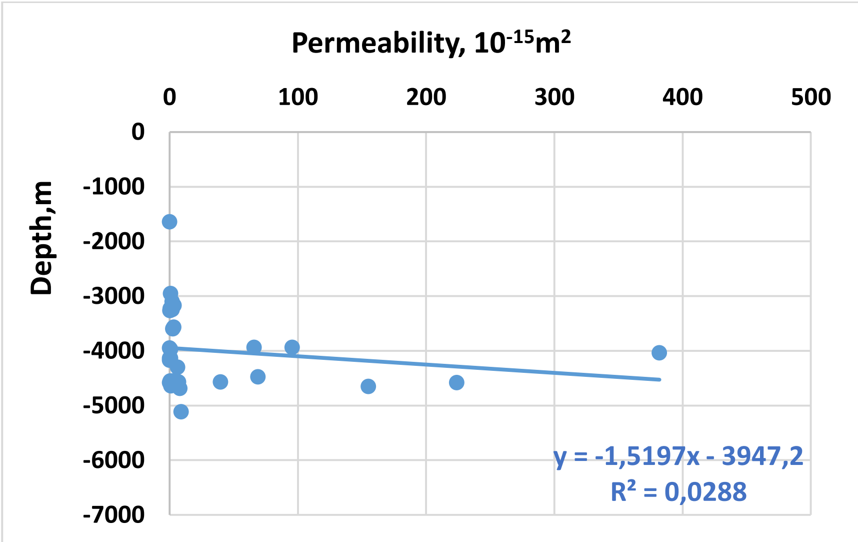


Figure 3: *Graph of the dependence of rock porosity and permeability on the occurrence depth in the Sangachal-deniz field*

In the Duvanny-deniz field, the rocks that make up the section, with the exception of some occurrences, are highly porous. The porosity of clayey-silty sandstones varies within 17-34%, while the porosity of clayey-silty sandy loams, clayey-sandy aleurolits and clayey aleurolits varies within 16-25%, 18.0-30.0% and 30.3-23. 0% accordingly. Despite the fact that the content of the fraction finer than 0.01 mm is 63%, the porosity in most cases is over 17%. The distinctive nature of the field section is noted at a depth of 3632 m, where porosity and permeability are higher (23% and $541 \cdot 10^{-15}$ m^2, respectively) (Fig.4). As noted above, this depends on the degree of fracturing of the rocks composing the field section. It should be noted that under this condition, the permeability of the rock is higher and amounts to $166\text{-}167 \cdot 10^{-15}$ m^2; in some cases, the permeability value reaches up to $266\text{-}294 \cdot 10^{-15}$ m^2 due to the appearance of additional cracks with depth in the rocks.

Manifestations of the chlidolite fraction smaller than 0.01 mm negatively affect the permeability of rocks, so that the permeability decreases to $42 \cdot 10^{-15} m^2$, even in some cases to $2.2 \cdot 10^{-15} m^2$. The distinctive character of the Duvanny-deniz field section is the presence of silty-sandy loams (fractions finer than 0.01 mm are 45.3%), which has a bad effect on the permeability of rocks.

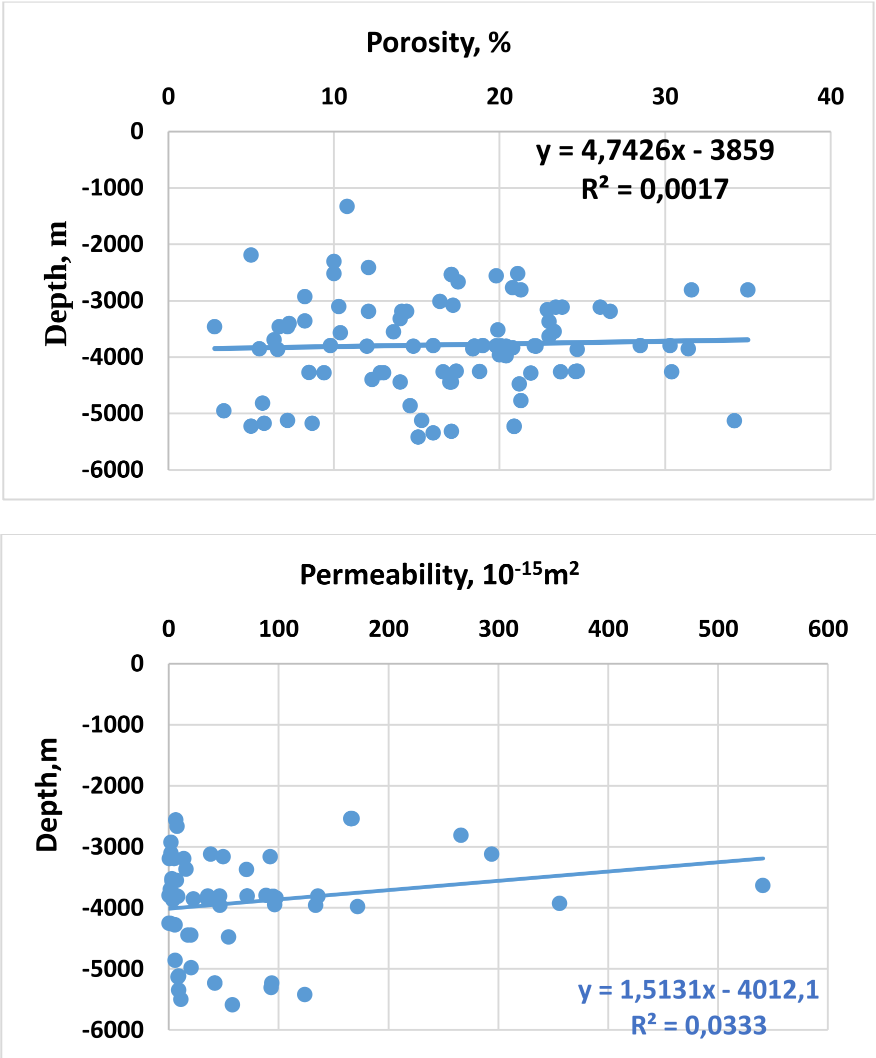

Figure 4: *Graph of the dependence of rock porosity and permeability on the occurrence depth in the Duvanny-deniz field*

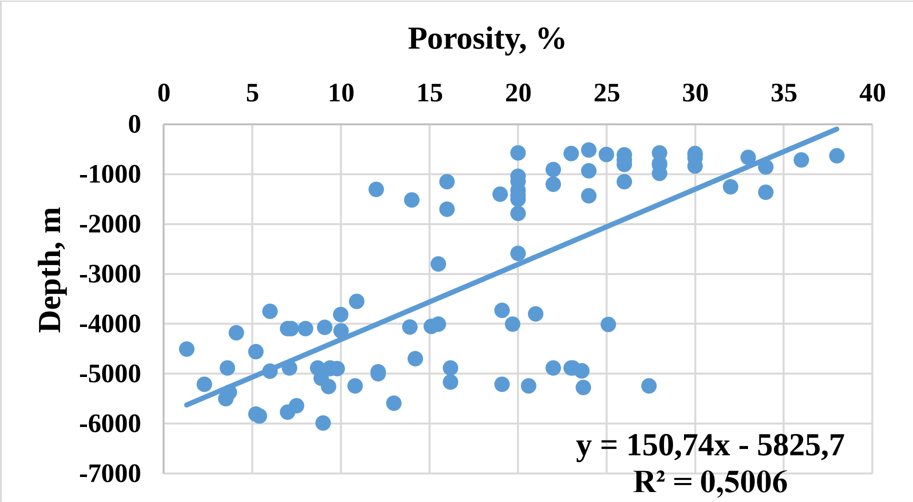
With the exception of some depths along the section from top to bottom, clayey-sandy subaleurolits with a porosity of 12.0-20.8% are observed with a higher content of the fraction finer than 0.01 mm (35.5%) in the range of 5.0-9.0%.

The carbonate content of sediments along the section of the field varies from 4.2% to 25.4%.

Deposits of the Productive series, deposits of the Absheron and Gadim Khazar stages are wide spread along the Khara-Zira field [3, 16]. The section of the structure consists of rocks similar to previous fields.

In all cases, terrigenous rocks are permeable. The permeability of rocks along the section of the area varies between of 0.1-267·10^{-15} m^2 with the exception of some depth intervals. Analysis of core materials taken from great depths (4982-4988 m) showed that despite the presence of clay fractions, the permeability of reservoirs (sands and sandstones) varies in a wide range of 132-1910·10^{-15} m^2, which is an indicator of a high degree of sorting of reservoir rocks, as well as fracturing of clayey deposits. In this case, the porosity of the rocks is 16.2-23.1%. The porosity of clayey-silty sandstones and clayey aleurolites along the field section ranges from 23-34% and 28-38%, respectively (Fig.5).

From the above it follows that the amount of clayey-sandy aleutolites and clayey rocks varies for different fields. At the same time, the physical properties of these rocks vary in a wide range [15]. This difference is shown to be due to varying degrees of compaction and occurrence depth of the sediments. Lithological differences in sediments are compacted to varying degrees under the same geological conditions. With depth, the clays compact at first very quickly, then slowly. It should be noted that in some places this pattern is violate; compaction accelerates and then slows down. Sandstones and coarse-grained aleurolites containing other small fragments are compacted to a lesser extent, and their porosity is reduced by an average of 2-3% for every 700-800 m.



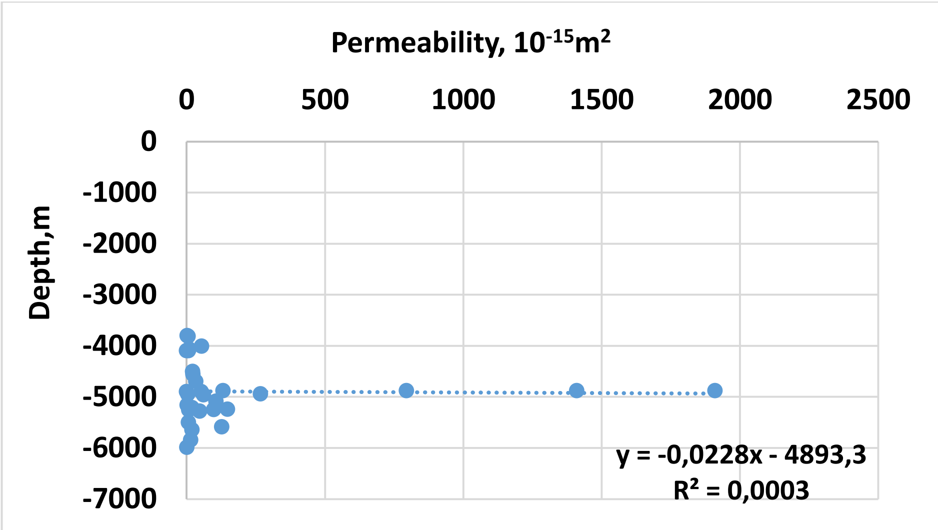


Figure 5: *Graph of the dependence of rock porosity and permeability on the occurrence depth in the Khara-Zira field*

As can be seen from the plotted graphs, the relationship between rock permeability and burial depth is less clear, but in general the pattern remains the same- the greater the burial depth, the lower the permeability of terrigenous rocks (see, Fig. 2, 3, 4).

V. Conclusions

1. Depending on the depth, the increase in the density of rocks under the influence of geostatic pressure leads to a decrease in their porosity and permeability. Compaction of different types of rocks occurs with unequal intensity.

3. At great depths (over 4900 m), due to subsidence in sands, sandstones and clayey sandstones, a very wide range of changes in porosity and permeability is observed in the Khara-Zira deposits. This circumstance is an indicator of industrial accumulation and must be taken into account when assessing the prospects for oil and gas potential.

4. There is no regulation in changes in porosity and permeability with depth, which is associated with the lithology of the rocks.

5. With increasing burial depth, porosity increases in places. This is due to the fracturing of rocks under the load of overlying rocks.

6. The cementing material (carbonate content, chlidolite fraction, tiny particles, loam, sandy loam) greatly affects the permeability and porosity of terrigenous rocks, and at different depths it varies. The greater the depth of the rocks, the less cement they must contain in order for them to be permeable.

Abstract

The article is devoted to the issues of modeling the optimization of economic potential of the enterprise on the basis of matrix algorithm of decision-making. The article considers the final stage of algorithmization of system-scenario multifactor modeling of optimization of economic potential on the basis of strategic decision-making matrix, which includes analytical tools for point positioning of the level of economic potential development in the context of variability of complex analytical scenarios of growth of potential-efficiency of the enterprise taking into account the factors of globalization and international integration.

At the enterprise level the optimization strategic task of economic potential management is solved, which provides for the use of more detailed decomposition of economic potential, a wide range of indicators taking into account the specifics of the enterprise's activity, accurate determination of the values of the elements of potential. The development of economic and mathematical model of economic potential management at the level of textile industry enterprises is made in accordance with the general theory of systems.

In order to optimize management, modeling interactions between the parameters of the economic potential of textile enterprises is an effective management tool and relates to solving the task of targeted management related to the multilevel system of private criteria, their unequal value, the need to simultaneously take into account both quantitatively and qualitatively specified indicators of private potentials. Based on this definition, further modeling of economic potential and methods of its analysis are possible.

The model experiment allowed us to develop a scenario series of optimization of economic potential according to the criterion of growth potential-efficiency of its development level in the future; to carry out typologization of the description of functional tools of market strategies.

Keywords: economic potential, matrix, dynamics, development, potential-efficiency, index, optimization, strategic scenario, means of scenario development

I. Introduction.

The development of the theory and practice of system optimization modeling of the economic potential (EP) of microeconomic objects is considered an urgent direction of designing an information and analytical decision support system (IA DSS). In this context, the microeconomic system is considered as an object possessing dynamically developing economic potential and having the result of its level of development, quantifiably measured by potential efficiency.

Economically competent use of the EP optimization theory allows you to anticipate changes in the target indicators of its development.

The purpose of the study is to develop the optimization of the EP of microeconomic systems based on the strategic decision-making matrix integrated into the IA DSS of the enterprise.

The tasks are set: to develop the format of a strategic matrix for managing the development of economic potential in a system of indicators of market and factor potentials (a two-dimensional model of the efficiency of using the level of economic potential); to deduce the threshold values of the integral index of market potential in the procedure of typology of enterprises; to present conceptual approaches to diagnostics based on the matrix of management decisions in the subsystem for developing strategic scenarios.

II. METHODS AND MATERIALS

The EP optimization model goes through a number of stages of algorithmization of analytical information processing, the final of which is the positioning of the level of development of the economic potential of microeconomic systems in the matrix of decision-making strategies. This stage of the IA DSS design algorithm in the subject area of EP optimization is preceded by the following blocks: a hierarchical model of a multi-criteria assessment of economic potential, which includes five levels of disaggregation of a generalized target criterion; fuzzy mathematical modeling and multi-criteria analysis of the market and factor potentials of microeconomic systems; mathematical modeling and analysis of the dynamics of integral indicators of the level of EP development in decomposition; econometric mathematical model and multifactorial correlation and regression analysis of EP optimization.

Economic and mathematical information processing based on the strategic decision-making matrix provides for setting goals, directions and criteria for the development of the EP microeconomic system; designing a matrix of decision-making strategies with subsequent positioning of the level of development of the EP microeconomic system; effective implementation of complex data analysis scenarios based on optimizing the pace and proportions of the development of integral indicators of market and factor potentials with step-by-step detailing of production, human resources, innovation and investment potentials; design of a DSS for optimizing the EP of a microeconomic system of fuzzy data analysis scenarios.

The target vector of optimization of the EP microsystem of the enterprise in the study provides for ensuring its sustainable development in the long term: increasing investment and export attractiveness, increasing the efficiency of using EP (based on the criterion of intensification) for all elements of decomposition; the criterion of EP development is focused on the outstripping growth of the integral indicator of market potential relative to the growth rate of the integral indicator of factor potential, provided an optimal combination of production, personnel, innovation and investment potentials; building up innovative and investment potentials in accordance with the design and target vector of EP development; system-scenario multifactorial modeling of EP optimization taking into account the factors of globalization and economic integration (points of growth of integration ties in the format of the Union State, the Eurasian Economic Union).

The matrix of EP optimization strategies at the micro-level of the enterprise is designed based on the selected decomposition of the EP, the hierarchy of structural elements, a sufficiently deep format for detailing the estimated parameters of the level of development of the EP, the characteristics of internal and external factors. Integrated indices of market potential development (characterizes the market effectiveness of using the EP system, taking into account the dynamics of the enterprise's market share under the influence of factors of globalization and integration) and factor potential generated on the basis of indices of the development of production, personnel, innovation and investment potentials (characterizes the dynamics of resource capabilities of the EP systems that ensure the production competitiveness of products and the rating of their positioning in the market).

The author's matrix of decision–making strategies has the property of a high degree of detail and sensitivity of the dimensional scale of the quadrants in accordance with the coordinate points of the selected indicators: a dependent variable is an integral indicator of the development of market potential, an independent variable is an integral indicator of the development of factor potential; implements the relationship "the level of development of the EP – the efficiency of the use of the EP – the effectiveness of the functioning of the microeconomic system".

The positioning of the EP development level at the enterprise level is detailed taking into account the developed information and analytical environment in the matrix field of coordinates: the typologization format is tied to the boundaries of the 16 quadrants of the matrix (high level of development, above average level of development, below average level of development, low level of development). Each quadrant of the matrix is subject to economic interpretation in accordance with a combination of interval values of integral indices of market and factor potentials, given in the graph of characteristics of the zones of the field of the strategic decision-making matrix.

For each type of interval values of integral indices, taking into account external and internal factors, a vector of scenarios for the development of EP was selected and a market strategy for optimizing EP was adapted. The concept of diagnostics based on the decision-making matrix in the subsystem for the development of strategic scenarios for the development of EP includes the specification of: quadrant zones; typology of the microeconomic system according to the intervals of values of integral indices of EP; characteristics of the zones of the field of the strategic matrix according to the values of indicators; the content of the strategy and the vector of scenarios for the development of EP, taking into account the balance of the indicators of the matrix.

In the conducted research, the IA DSS optimization of the EP was carried out on the basis of the use of strategic scenarios in the following areas: pessimistic and optimistic. The format of the pessimistic scenario reflects the target indicators of EP development in quadrant a) (normalized indices of market and factor potentials, respectively, Irp [0÷0.5]; Ifp [0÷0.5]); optimistic scenario – in quadrant b), d), c) (normalized indices of market and factor potentials, respectively, Irp [0.5÷1.0]; Ifp [0.5-1.0]).

The starting point for scenario design is the position of the enterprise's EP development level in the coordinate system of the strategic matrix in the reporting period (the state of the EP at the endpoint of the dynamic series). The projected trajectory of movement in the strategic field of the matrix is set in accordance with the chosen EP optimization strategy and the variability of scenarios based on the genetic and target development options. The criterion of the positivity of the development of EP potential is the target integral indicator of economic potential, the increase of which corresponds to the increase of EP, taking into account the factors of globalization of production and interregional integration.

III. LITERATURE REVIEW

The study was based on the analysis of the works of Andreychikov et al. (1998), Bruskin (2016), Zadeh (1976), Mereste (1982), Chegerova (2021), Diligensky et al. (2004), Saati (1991), Kerns (1991), Savitskaya (2023), Finogenko (2017) in the field of system analysis, information and analytical system design and decision theory. The theory of market management strategies is considered in the works of Kuroedov et al. (2007). Some methodological aspects of economic potential assessment have been studied by scientists: Afinogenov et al. (2019), Khvorostov (2005), Gorbunova (2014), Vapne (2019), Gonin et al. (2014),), Sheshukova et al. (2013), Shcherbakov et al. (2019), Kovalev et al. (2006), Morozova (2009), Mogilina (2015), Nizamutdinov (2017), Peshkova (2017), Pisareva (2018), Rakhmanova (2018), Tashkinov (2018), Terekhova-Pushnaya (2019), Podolsky et al. (2020), Yarygina (2016), Gurieva (2018), and others.

The lack of a systematic theoretical and methodological approach to mathematical modeling of dynamic processes of the state and changes in economic potential, providing a genetic format for optimizing its development, actualizes the tasks of scenario modeling of optimization of EP enterprises.

IV. RESULTS AND DISCUSSION

The information base of the model experiment was the reporting data of textile industry enterprises: 56 factors were identified, rolled up on the basis of the fuzzy modeling method into integral indices of market, production, personnel, innovation and investment potentials with access to global factor potential (Table 1); a polynomial regression relationship between market and factor potentials was established, which was used to calculate target indicators in enterprise EP optimization scenarios.

The structural model of IIP quality in the cluster of analyzed textile industry enterprises showed a fairly high spread of integral parameters of local potentials (for example, the spread of the level of the integral indicator of investment potential development by enterprises for 2019-2023 was stated from

0.0014 (enterprise 3) to 1.0059 (enterprise 1). The average annual rate of change in the integral indicators of market and factor potentials in the decomposition indicated imbalances in the dynamics and prospective scenario development of the EP.

Diagnostics of integral indicators in the dynamics of 2014-2023 for enterprises of the textile industry is characterized by the following provisions:

- enterprise 1: the most significant increase in the integral indicator is attributed to production potential (11.26%) with a simultaneous lag in personnel, innovation and investment potentials, which corresponds to a low level of growth in market potential (average annual growth rate of 100.38%);
- enterprise 2: high levels of innovation and investment potentials are indicated (the average annual increase, respectively, amounted to 2.84; 5.33%); low levels and intensity of dynamics in terms

of personnel potential and the rate of decline in terms of market productive potential (an average annual relative decrease of 2.48 %;

- enterprise 3: the general profile of integral indicators shows the active dynamics of the development of market potential (average annual growth rate of 102.25%) with a significant lag in the development of innovative, investment, human resources and production potentials.

The harmonious development of the economic potential of the microeconomic systems of enterprises as a whole is designed in the scenario format of the predictive development of the EP.

The regulations for the construction of strategic scenarios for the optimization of the EP included:

- the target values of the integral indicators of production, personnel, innovation, and investment potentials are set in accordance with the structure of the elements of factor potential corresponding to the largest value of the integral index of market potential in a series of dynamics over 10 years using the method of structural analogy;
- calculation of integral indicators of production, personnel, innovation, investment potentials was carried out in accordance with the boundaries of target indicators, the point of positioning of the enterprise in the strategic decision-making matrix for optimizing the EP in the last year of the studied series of dynamics and the optimal structure of factor potential;
- calculated values of the integral index of market potential are determined based on econometric models of regression dependence;
- interval grouping of target indicators was performed in groups of scenarios pessimistic, optimistic: the boundaries of the intervals are reduced to the format "lower bound – upper bound";
- the lower limit of the target integral indicator of factor potential is established based on the calculated values of the integral indices of production, personnel, innovation and investment potentials linked to the boundaries of the quadrants of the strategic matrix and the optimal structure of the factor potential of the analyzed enterprises;
- when designing the upper limits of the target indices of production, personnel, innovation and investment potentials, we proceeded from the balance of gains in the indices of market and factor potentials;
- based on the obtained regression dependence, the calculation of the lower and upper limits of the target market potential indices was performed;
- the target index of factor potential is calculated by multiplicative convolution using established significance coefficients;
- scenarios of target indicators for the optimization of EP enterprises: a set of target indices for the development of EP in tabular form (working out for the enterprise 1 table 2);

- the development and specification of the content of EP optimization strategies was carried out in accordance with the developed typologization of functional tools for the growth of potential efficiency of microeconomic systems.

As an indicator controlling the level of positivity (growth) of the efficiency potential in the mathematical model, the target integral indicator of the EP was adopted, the value of which, in the context of the studied enterprises, was distributed in the following directions:

- enterprise 1) is achieved already at the first point of the scenario format: the increase in the integral indicator of the EP along the lower; upper boundary, respectively, amounted to 3.36; 11.04% relative to the average value of the parameter for a number of dynamics over 10 years; in the group of optimistic scenarios, the growth of the integral indicator of the EP by more than 2 times (the highest value corresponds to the 12 scenario with a conglomerate diversification and an increase in the generalizing parameter along the boundaries by 3.80; 4.14 times, respectively);

- enterprise 2) is achieved at the second point of the scenario format: the increase in the integral indicator of the EP along the lower; upper boundary, respectively, amounted to 7.10; 17.68%; the increase in the group of optimistic scenarios ranges from 124.94 to 291.30 %;

- enterprise 3) is achieved at the second point of the scenario format: an increase of 9.41; 14.97%; a variation of the relative increase in the group of optimistic scenarios – from 74.11 to 150.33%.

V. CONCLUSION

Thus, a model for optimizing the economic potential of an enterprise based on a strategic decision-making matrix, designed based on the synthesis of the theory of fuzzy sets, the method of hierarchy analysis, the method of scenario verification of forecasts, which allows you to position the economic potential of an enterprise in a strategic matrix with a high level of reliability and select a scenario trajectory of the program-target vector of optimization of economic potential according to the criteria of economic growth taking into account the factors of globalization of production in the industry.

Testing of the developed system-scenario multifactorial model of EP optimization in the information field of textile industry enterprises has shown: the genetic variant is characterized by a low level of economic potential efficiency, negative dynamics of a decrease in integral indicators, an imbalance of structural elements in the decomposition, subject to significant fluctuations in indicators.

In the prognostic direction, an algorithm of scenario verification is undertaken when making decisions to optimize EP in the system of strategic development of market factors of globalization and international integration. During the model experiment, the developed scenarios are filled with functional tools for increasing the potential efficiency of the system in accordance with the types of strategies.

ON THE PROBABILITY OF COLLAPSING OF SUPPORTS IN A PIPELINE MOUNTED ON FLEXIBLE SUPPORTS

taghizadeu@mail.com

Abstract

When laying pipelines using concrete supports and frames in the overhead laying scheme, the pipes may experience deformation and tension due to the height at which they are installed, typically between 1.0-1.5m from the ground surface. The installation of overhead pipeline on hard or collapsible foundations causes bending due to the combined weight of the pipes and the transported product. This text discusses the use of three moment equations to solve this problem.

Keywords: pipeline, support, bending moment, supporting reaction, collapse coefficient

I. Introduction

Experience indicates that supports installed on pipelines operated at hazardous production facilities commonly exhibit the following types of defects:

- corrosion damage to support elements [1-3]
- external corrosion of pipelines in the area of supports
- failure of welded joints of support elements welded along the pipe;
- crushing;
- slipping of pipelines from support surfaces;
- collapse of supports;
- failure of hangers, etc.

It is widely acknowledged that the three moment equations can be expressed as [4-6]:

$$M_{n-1}l_n + 2M_n(l_n + l_{n+1}) + M_{n+1}l_{n+1} =$$
$$-6\left(\frac{\omega_n a_n}{l_n} + \frac{\omega_{n+1}b_{n+1}}{l_{n+1}}\right) - 6EJ\left(\frac{\Delta_{n+1}-\Delta_n}{l_{n+1}} - \frac{\Delta_n-\Delta_{n-1}}{l_n}\right) \quad (1)$$

Here: Δ, $\Delta_{n-1}, \Delta_n, \Delta_{n+1}$-collapse of supports, i.e., vertical displacement of supports as a result of rock collapse;EJ - is the hardness of the pipe.

According to Winkler's hypothesis, vertical subsidence can be calculated as:

$$\Delta_n = R_n \cdot \delta \quad (2)$$

Here: R_n-support reactions, δ-rock (soil) settlement capacity, $m/k\,N$.

It is evident that the support collapses due to the displacement of the rock. As shown in expression (2), the collapse of the support is directly proportional to its reaction. [7-8]

II. Methods

Let 's consider the beam (pipeline) installed on rubber supports (Fig . 1).

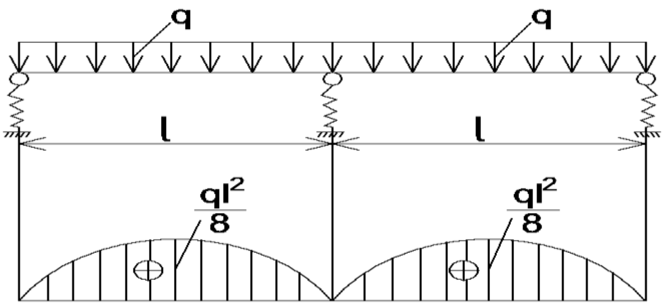

Figure 1: *Pipeline on elastic supports*

If the load on a beam is evenly distributed across its spans, the three moment equations for a beam with *n* spans and a distance of l_n between supports are as follows:.

$$M_{n-1}l_n + 2M_n(l_n + l_{n+1}) + M_{n+1}l_{n+1} = -6\left(\frac{\omega_n a_n}{l_n} + \frac{\omega_{n+1}b_{n+1}}{l_{n+1}}\right) \quad (3)$$

Here, ω_n -q represents the areas of the bending moment curves caused by the load. a_n represents the distance from the center of each epur to the left support, while b_{n+1} represents the distance from the center of each subsequent epur to the right support.

$$\omega_1 = \omega_2 = \omega_3 = \cdots = \omega_{n-1} = \omega_n = \frac{2}{3}\frac{ql^2}{8}\cdot l = \frac{ql^3}{12},$$

$$l_1 = l_2 = l_3 = \cdots = l_n = l, a_1 = b_2 = a_2 = b_3 = \cdots = \frac{l}{2}$$

$$\frac{\omega_n a_n}{l_n} = \frac{\omega_{n+1}b_{n+1}}{l_{n+1}} = \frac{ql^3}{12}\cdot\frac{l}{2\cdot l} = \frac{ql^3}{24}$$

Starting from this point, we can write:

$$\frac{\omega_1 a_1}{l_1} + \frac{\omega_2 b_2}{l_2} = \frac{ql^3}{12}, \qquad 6\frac{ql^3}{12} = \frac{ql^3}{2}$$

According to Figure 2.5, we can write using expression (1):

$$\frac{\Delta_{n+1} - \Delta_n}{l_{n+1}} - \frac{\Delta_n - \Delta_{n-1}}{l_n} = \frac{\Delta_2 - \Delta_1}{l} - \frac{\Delta_1 - \Delta_0}{l} = \frac{1}{l}(\Delta_2 - 2\Delta_1 + \Delta_0)$$

According to formula (3).

$$\Delta_2 - 2\Delta_1 + \Delta_0 = \delta(R_2 - 2R_1 + R_0)$$

In Figure 2.5, since $M_0 = M_2 = 0$, we can express the reactions as follows:

$$R_2 = \frac{1}{l}\left(\frac{ql^2}{2} + M_1\right) = R_0,$$

$$R_1 = \frac{1}{l}(ql^2 - 2M_1)$$

and

$$R_2 - 2R_1 + R_0 = \frac{1}{l}(-ql^2 + 6M_1)$$

In this case, formula (1) can be written as follows :

$$4M_1 = -\frac{ql^2}{2} - \frac{6EJ\delta}{l^2}(R_2 - 2R_1 + R_0) = -\frac{ql^2}{2} - \frac{6EJ\delta}{l^3}(-ql^2 + 6M_1) \quad (4)$$

$\frac{6EJ\delta}{l^3} = \eta$ If we sign with , we get :

$$4M_1 = -\frac{ql^2}{2} + \eta ql^2 - 6\eta M_1.$$

or

$$M_1(4+6\eta) = -\frac{ql^2}{2}(1-2\eta)(5)$$

Consider its effect on the stiffness of the supports (EJ) by setting different values of the settlement coefficient δ:

1. $\delta = 3 \cdot 10^{-4}$ m/kN ; $ql^2 = 2060\ kNm$; $E = 2{,}1 \cdot 10^5\ MPa$; $J = 57 \cdot 10^{-4} m^4$; $l = 20m$; $\eta = 0{,}425$.

Then

$$4 + 6\eta = 6{,}55; 1 - 2\eta = 0{,}15$$

becomes and we get $M_1 = -47{,}2\ kNm$

M_1 a small value of the moment indicates that the stiffness of the elastic support is low. In order to increase the hardness, let's accept the value of the coefficient of collapse of the rock as small:

2. If $\delta = 2 \cdot 10^{-4}\ m/kN$if, then $\eta = 0{,}2835$ and $M_1 = -156{,}46\ kNm$. The bearing moment value increase suggests that as the subsidence coefficient decreases, the rock stiffness increases. This causal relationship indicates that the bearing moment also increases.. It should be noted that the stiffness of the pipe and the stiffness of the rock (elastic support) are different concepts.

If the supports were not elastic in the considered case:

$$M_1 = -\frac{ql^2}{2} = -2060 kNm \text{and} M_1 = -515 kNm$$

would be taken. This means that large flexibility cannot be allowed, that is, as the coefficient of collapse increases, the pipeline can bend more. As a result, it is inevitable that greater stress and deformations will occur in the pipeline. Therefore, it is necessary to increase the stiffness of the supports as much as possible.

Let's consider the calculation of the support moment generated at one transition of the pipeline on elastic supports (Fig. 2).

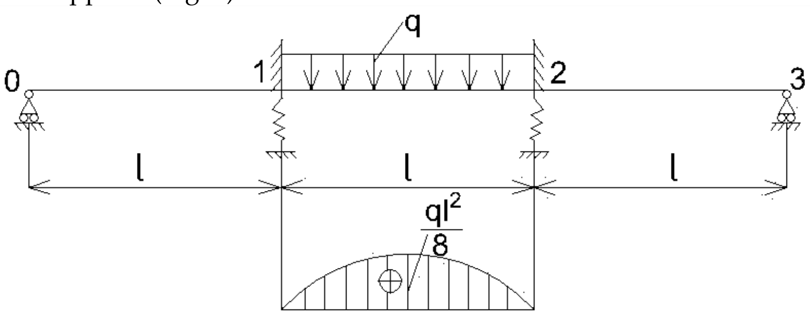

Figure 2: *A pipeline span on elastic supports*

Applying formula (1), we can write down the following expressions from Figure 2:

$$\begin{cases} 2M_1 + M_2 = -\dfrac{ql^2}{4} - 2\eta(M_1 - M_2) \\ M_1 + 2M_2 = -\dfrac{ql^2}{4} - 2\eta(M_2 - M_1) \end{cases}$$

and:

$$\begin{cases} 2(1+\eta)M_1 + (1-2\eta)M_2 = -\dfrac{ql^2}{4} \\ (1-2\eta)M_1 + 2(1+\eta)M_2 = -\dfrac{ql^2}{4} \end{cases}$$

Assuming $\delta = 1 \cdot 10^{-4} sm/kq$, then $\eta = 0{,}142$ and

$$\begin{cases} 2{,}284M_1 + 0{,}716M_2 = -103 \\ 0{,}716M_1 + 2{,}284M_2 = -103 \end{cases}$$

will be. Hence $M_1 = -M_2 = -341kNm$. This means that when the core fracture ratio is small, the bearing moment increases.

Applying equation (1) to the pipeline (beam) on the supports shown in Fig. 3 and making the appropriate transformations yields the following system of equations for this beam:

$$\begin{cases} 2(1+\eta)M_1 + (1-3\eta)M_2 + \eta M_3 = -(1+2\eta)\dfrac{ql^2}{4} \\ (1-3\eta)M_1 + (4+6\eta)M_2 + (1-3\eta)M_3 = -(1-2\eta)\dfrac{ql^2}{2} \\ \eta M_1 + (1-3\eta)M_2 + 2(1+\eta)M_3 = -(1+2\eta)\dfrac{ql^2}{4} \end{cases}$$

$$\eta = \frac{6EJ\delta}{l^3}; \delta = 1 \cdot \frac{10^{-4}m}{kN}; \frac{ql^2}{4} = 1030kNm$$

by accepting

$$\frac{ql^2}{2} = 2060kNm$$

etc. by solving the required equations ,

$$M_1 = M_2 = M_3 = -343\ kNm$$

we get

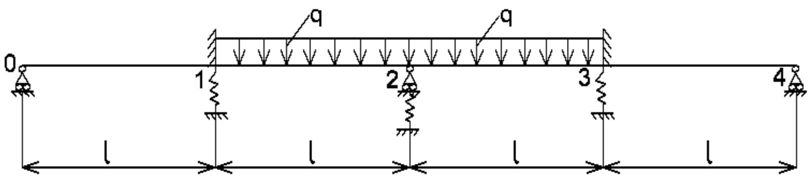

Figure 3: *Two spans of the pipeline on elastic supports*

III. Results

The impact of the settlement coefficient's smallness on the support moments' value is evident. Additionally, the support moments' calculation indicates that all transitions are under the same conditions and subject to the same effects. The rock's inability to subside corresponds to the subsidence coefficient's small value.

Dostoevsky Omsk State University, RUSSIA
natalie_v_al@inbox.ru

Abstract

In the context of rapid technological advancement and global environmental challenges, digital identity emerges as a crucial tool for promoting sustainable behavior. Digital identity refers to the way individuals express themselves and interact within the online space, influencing their actions and choices in the real world. This paper explores various aspects of digital identity, including its impact on the formation of sustainable habits and practices, the enhancement of environmental awareness, and the development of social responsibility. It analyzes how social media platforms and digital technologies can be utilized to create communities that foster the exchange of sustainable practices and ideas. Additionally, the challenges related to data security and privacy that may affect the use of digital identity in achieving environmental goals are discussed. In conclusion, the necessity of integrating digital identity into strategies for promoting sustainable behavior is emphasized, as it can contribute to a more conscious and responsible relationship with the environment.

Keywords: digital identity, sustainable behavior, environmental awareness, social media

I. Introduction

In an era defined by rapid technological advancement and escalating environmental challenges, the urgency to promote sustainable behavior has become paramount. The world faces a myriad of pressing issues, including climate change, resource depletion, pollution, and biodiversity loss. These challenges necessitate innovative and effective approaches to inspire individuals and communities to adopt more sustainable practices. One promising avenue is the integration of digital identity into sustainability efforts. As societies become increasingly digitized, understanding how digital identity can shape behaviors and attitudes toward the environment is essential.

Digital identity refers to the online persona that individuals cultivate through their interactions on various digital platforms, including social media, forums, and other online communities. This identity encompasses not only personal information but also the values, beliefs, and behaviors individuals express in the digital realm. With the advent of social networks and online communication, people are no longer passive consumers of information; they actively engage, share, and influence one another's behaviors. This engagement provides fertile ground for promoting sustainable practices, as individuals can leverage their digital identities to advocate for environmental issues and inspire change.

Digital identity can significantly impact sustainable behavior in several ways. First, it influences how individuals perceive themselves in relation to sustainability. When people align their digital identity with eco-friendly values—such as reducing waste, conserving energy, and supporting local businesses—they are more likely to adopt these behaviors in real life. For instance, individuals who showcase their sustainable practices online may feel a heightened sense of accountability to continue these actions, as their peers reinforce these behaviors through likes, shares, and comments.

Additionally, digital identity fosters community building around shared sustainability goals. Online platforms enable individuals to connect with like-minded people, forming communities that support and encourage sustainable practices. These communities can facilitate the exchange of ideas, resources, and information about sustainable living, creating a sense of belonging that motivates individuals to engage in environmentally friendly behaviors. As these digital communities grow, they can amplify their collective influence, driving broader societal change.

Another critical aspect of digital identity's role in promoting sustainable behavior is its capacity to raise awareness about environmental issues. Digital platforms serve as powerful channels for disseminating information about sustainability, from climate science to local conservation efforts. Influencers, activists, and organizations can use their digital identities to share compelling narratives, engage followers, and mobilize action. This can include campaigns to reduce plastic use, promote renewable energy, or support wildlife conservation initiatives.

Moreover, digital identity enables the sharing of educational resources, helping individuals understand the impact of their choices on the environment. Online tutorials, webinars, and interactive content can provide valuable insights into sustainable practices, making it easier for individuals to incorporate eco-friendly habits into their daily lives. By harnessing the power of digital identity, individuals can become informed advocates for sustainability, influencing others and contributing to a larger movement toward environmental responsibility.

Despite its potential, the integration of digital identity into sustainability initiatives is not without challenges. Privacy concerns are paramount, as individuals may hesitate to share personal information or engage in online discussions about their eco-friendly choices due to fears of data misuse or surveillance. The need for robust data protection measures is essential to ensure that individuals feel safe in expressing their digital identities.

Furthermore, the phenomenon of "greenwashing" poses a significant challenge. As businesses and organizations increasingly adopt sustainability messaging, discerning authentic commitments from superficial marketing tactics can be difficult for consumers. Digital identity can inadvertently contribute to this issue, as individuals may align their online personas with sustainable practices that do not reflect their real-world behaviors. This disconnect can undermine the credibility of sustainability efforts and diminish trust in digital advocacy.

II. Methods

To explore the role of digital identity in promoting sustainable behavior, three distinct methods were employed: survey analysis, interviews and focus groups, and case study analysis. Each method contributed unique insights into the relationship between digital identity and sustainable practices.

1. Survey Analysis

A comprehensive survey was distributed across various demographic groups to gather quantitative data. The survey included questions on digital identity usage (e.g., social media, digital platforms) and sustainable behaviors (e.g., recycling, energy conservation, ethical consumption). Respondents were asked about:

How often they engaged with digital platforms that focus on sustainability.

Whether their online identity influenced their real-world sustainable actions.

Perceived barriers to adopting eco-friendly behaviors through digital means.

Analysis: The data was statistically analyzed to find correlations between digital engagement and sustainable behavior, using regression models and cross-tabulation to identify trends across different age groups, education levels, and regions.

2. Interviews and Focus Groups

Semi-structured interviews and focus group discussions were conducted with key participants, including sustainability advocates, environmental researchers, and digital platform developers. These qualitative methods provided a deeper understanding of:

Personal experiences with how digital identity influences their commitment to sustainable practices.

Motivations for engaging in online sustainability communities and how digital identities shape those motivations.

Challenges and opportunities faced in promoting eco-consciousness through digital identities.

Analysis: Thematic analysis was employed to identify common themes such as social accountability, digital peer influence, and the impact of digital rewards systems on promoting environmentally responsible behavior.

3. Case Study Analysis

Several case studies of digital platforms that successfully promote sustainability (e.g., apps or websites dedicated to green living, carbon footprint tracking, or ethical shopping) were analyzed. The focus was on:

How these platforms construct and maintain user digital identities that align with environmental values.

The mechanisms used to encourage sustainable actions, such as gamification, social sharing, or incentives.

The long-term impact of these platforms on user behavior and environmental outcomes.

Analysis: Comparative analysis was conducted across case studies to evaluate which strategies most effectively integrate digital identity with sustainable behavior. Specific factors such as user engagement levels and measurable environmental impact were compared.

By combining these three methods, the study offers a comprehensive understanding of how digital identity can drive sustainable behavior and what strategies can further enhance this connection.

III. Results

Although discussions on sustainability and its relevance began to surface prominently towards the end of the last century, particularly with the 1972 Stockholm Conference organized by the United Nations (UN) (Rodrigues, 2009), concerns regarding this issue actually date back to the first (1760-1840) and second (1850-1945) industrial revolutions. The industrial revolution led to a dramatic increase in the production of goods and wealth, raising people's purchasing power. However, it also resulted in negative outcomes, including increased economic inequalities and significant environmental impacts due to heightened production. During this time, economists like John Stuart Mill (1848) and Thomas Malthus (1878) warned of the adverse effects that unchecked economic and population growth could have on both the environment and human well-being. Furthermore, the industrial revolution introduced a surge in consumption, making it a central aspect of economic development and shaping human relations. Mass production created an environment where consumerism—driven by the need to quickly dispose of goods—became normalized and encouraged. Over time, the satisfaction of personal desires began to take precedence over the fulfillment of genuine needs. This "consumerism," the ever-increasing production and acquisition of non-essential goods in pursuit of well-being, has since become a critical consideration within the sustainability discourse, as it places tremendous pressure on natural resources and the environment. Growing concerns over long-term environmental degradation sparked global events and environmental movements in the late 1960s and 1970s, which initiated widespread debates on the limits of growth and how environmental issues could be integrated into mainstream development goals. One significant milestone in this sustainability debate was the UN World Commission on Environment and Development's (WCED) 1987 "Our Common Future" report. It was one of the first comprehensive efforts to establish a global agenda for rethinking the human development model. The report defined sustainable development as development that "meets the needs of the present without compromising the ability of future generations to meet their own needs". It highlighted poverty in developing nations and rampant consumerism in developed countries as key factors preventing equitable development and causing serious environmental crises, which in turn sparked extensive academic and political discussions worldwide. This evolving sustainability discourse eventually found its way into business practices, with the introduction of the "Triple Bottom Line" concept. This framework expanded corporate objectives beyond just economic factors, proposing that sustainability involves the pursuit of economic prosperity, environmental protection, and social equity in an interconnected manner. In environmental terms, this approach urged businesses to preserve natural capital and maintain the planet's life support systems by balancing resource generation, consumption, and waste management.

IV. Discussion

Scientific and academic advancements in sustainability, alongside technological innovations and the rise of an eco-friendly culture, have fostered an environment where brands are increasingly motivated to address environmental issues and contribute to their resolution. Consequently, numerous online brand campaigns have emerged, wherein companies raise awareness about environmental challenges and strive to encourage sustainable behaviors among consumers. Many brands are now implementing pro-environmental initiatives, such as creating digital re-commerce platforms that promote conscious consumption.

However, while some brands successfully influence consumers' pro-sustainability behaviors through these actions, others fall into the trap of greenwashing, which can have detrimental effects not only on the brands themselves but also on consumers' willingness to engage in environmentally friendly practices. To ensure the success of their online environmental campaigns and effectively inspire pro-sustainability in their consumers, brands must establish a well-defined and authentic environmental purpose. This means aligning their communications with their actual practices to avoid inconsistencies. Specifically, brands must ensure that their environmental stance is congruent with their corporate identity, values, business operations, and overall mission. Additionally, brands must engage authentically and actively with the causes they advocate.

Lin emphasizes that companies should invest their resources and expertise in areas where they possess knowledge and a competitive advantage. They should also ensure that their internal policies align with the environmental purpose they wish to project in their campaigns. Collaborating with activists is crucial for understanding and fulfilling their collective moral responsibilities toward communities and the environment.

For brands to effect meaningful changes in consumers' pro-sustainable behavior, their environmental positions must be perceived as genuine and sincere. Authentic environmental activism requires maintaining a continuous alignment between a brand's stated intentions—reflected in its communication messages—and the actions it takes, such as implementing pro-environmental corporate practices, forming partnerships with environmental organizations, and supporting environmental initiatives.

Beyond establishing a coherent environmental purpose and maintaining authenticity, companies must communicate their environmental stances and actions effectively to ensure they resonate with the target audience and catalyze positive environmental changes. According to Key et al. (2021) and Taylor et al. (2001), brand activist communications should prioritize dialogic communication, facilitating ongoing interactions and providing relevant information to the target audience. Companies must understand how their audience receives and interprets their messaging, creating campaigns that align with consumers' expectations, experiences, and comprehension of the environmental issues at hand.

To encourage consumers to adopt pro-sustainable behaviors and commit to conscious consumption, brands should not only inform consumers about their environmental policies and the importance of the advocated environmental issues but also educate them on how to act and consume more sustainably. This could involve providing guidance on the responsible use and disposal of products. Additionally, brands must consistently convey their perspective across all online and offline communications, capturing and reinforcing the essence of their environmental stance with transparency and credibility. This includes highlighting their environmental strengths while also acknowledging areas for improvement.

In summary, companies need to be intentional in communicating their environmental positions and causes, grounding their messages in tangible evidence of their environmental performance. This could include third-party audits or ecolabels to reduce the risk of consumer alienation and enhance their capacity to drive pro-environmental behaviors. Given the significance of environmental communication within the realm of new digital platforms, particularly in market contexts, further investigation into how these platforms can facilitate or hinder pro-environmental change is essential. Future research could explore how brands' online environmental communication strategies impact various stakeholders, including employees and shareholders, analyze consumer reactions to greenwashing on social media, and examine whether such campaigns hinder conscious consumption by fostering skepticism. Additionally, studying how brands can make environmental issues more appealing to consumers through immersive technologies like augmented and virtual reality could prove valuable. Internally, it would be insightful to investigate how brands leverage digital technologies to reduce their ecological footprints, for instance, by enhancing internal communication regarding sustainability, improving supplier product breakage management, or optimizing distribution routes.

RESEARCH ON THE UTILIZATION OF SECONDARY ENERGY RESOURCES AND FUEL SAVING IN INTERNAL COMPUSTION ENGINE POWER PLANTS

Jamala Mamedova, Aytaj Allahverdiyeva (Malikova)

•

Azerbaijan State Oil and Industry University
cemile_adna@mail.ru
aytac_adna@mail.ru

Abstract

Heat of exhaust gases from stations operating with internal combustion engines (ICE) and heat of cooling water have been investigated in the paper. In such situations, 60% of the fuel heat is lost through the exhaust gas from the engines and cooling water. Various schemes are proposed for using this heat. When implementing these schemes, steam, hot water and cold can be obtained from waste gases. Then the efficiency of the station increases, specific fuel consumption and the amount of flue gases emitted into the atmosphere and environmental loads are reduced.

Keywords: diesel engines, flue gases, cooling water, fuel economy, efficiency, ecology

I. Introduction

Currently, in Azerbaijan, the majority of electricity is generated in steam turbine, combined, recycled, steam-gas and modular power plants with an internal combustion engine (ICE) [1]. Internal combustion engines of modular power plants are mainly used to maintain balance in the energy system. These stations are quickly launched and stopped quickly. In variable modes it is advisable to use such stations. ICEs of modular power plants mainly use natural gases.

Exhaust gases with a temperature of 500-520^{0}C are released into the atmosphere. Thus, in such stations, 50-60% of the fuel heat is released into the atmosphere by exhaust gas and cooling water and pollutes the environment. By using different schemes, heat of the flue gases can be used and ultimately the efficiency of the installation increases, specific fuel consumption and the environmental load are reduced.

II. Research

The studies were carried out at the Sangachal modular power plant with a capacity of 300 MWt. The station houses 18 four-stroke diesel engines. The power of each engine is 16.6 MWt. The engines run on gas. Below is the composition of the gas:

CH_4=93,9%; C_2H_6=3,1%; C_2H_8=1,1%; C_4H_{10}=0,3%; C_5H_{12}=0,1%; CO_2=0,2%; N_2=1,3%; Q^w_l=33500 kJ/m^3.

Each unit has a fuel consumption of B = 3500 m^3/hour. The temperature of the exhaust gas from the engine is 500^{0}C. Calculations were carried out according to [2].

For combustion of 1 m^3 of fuel, air consumption V_0=9.8 m^3/ m^3, the amount of flue gases produced during combustion is V_g=13.032 m^3/m^3. The excess air coefficient is accepted as α=1.2.

For stations, the total fuel consumption is:

B_{total}=18*3500=63000 m^3/hour.

The heat received in one unit is:

Q_{unit}=B* Q^w_l=3500*33500=117,25*10^6 kJ/hour.

The heat throughout the station is:

Q_{unit}=18* Q_{unit}=18*117,25*10^6=2110,5*10^6 kJ/hour=586,2 MWt.

A scheme is proposed for using the heat of exhaust gases from the engine and cooling water, it is shown in Fig. 1.

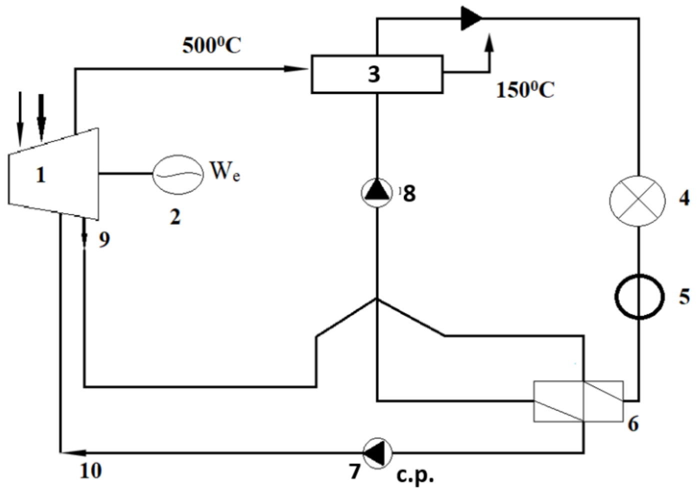

Figure 1: *Scheme of using the heat of exhaust gases and cooling water for heating and hot water supply*

1-Internal combustion engine; 2-electric generator; 3-recovery boiler; 4-heat consumer; 5-network pump; 6-heat exchanger; 7-circulation pump; 8-feed pump; 9-warm water leaving the engine (85-90^{0}C); cooled water (75-77^{0}C) for the engine.

The waste leaving the internal combustion engine at a temperature of 500^{0}C is fed into the waste heat boiler. The steam or hot water produced in the boiler is supplied to the heat consumer. From the consumer, condensate is supplied to the heat exchanger using a network pump. There, due to the heat of the cooling water leaving the engine, it is heated and supplied to the waste heat boiler using a feed pump. In the heat exchanger, the incoming hot water from the engine gives off its heat to the condensate, then cools and returns to the engine.

Enthalpy of gases entering the waste heat boiler [2]:

H_g=7963.67 kJ/m^3

The temperature of the gases leaving the boiler is accepted $t_{e.g.}$ = 150^{0}C, then the enthalpy of the exhaust gases is:

$H_{e.g.}$=2295 kJ/m^3

Then, when burning 1 m^3 of gas in a waste heat boiler, the heat used is:

ΔH=H_g-$H_{e.g.}$=5568 kJ/m^3; Q_g= B_{total}*ΔH=63000*5668.27 kJ/m^3=357*10^6 kJ/m^3=99 MW

Then heat savings

Δη=(99/586.2)*100%=16.8%

Gross station efficiency is η^{gr}_{st}=51%

When using exhaust gases from the engine, the gross efficiency of stations η^{gr}_{st}=51%+16.8%=67.8%

Specific fuel consumption under normal conditions:

V^{gr}_{st}=123/ η^{gr}_{st}=123/0.51=241 g/kW

When using exhaust gas heat

V^{gr}_{st}123/0.678=181.41 g/kW

Specific fuel consumption savings:

ΔV^{gr}_{st}=241-181.41=59.6 g/kW

Fuel savings across the entire station will be 17,880 T/h.

III. Calculation of heat loss of cooling water

In each engine, the cooling water leaves at a temperature of 85⁰C, is cooled in the heat exchanger to a temperature of 77⁰C and returns to the engine. Water circulates in the system for 120 T/h (Fig. 2).

In one engine the heat loss is:

Q=120 T/hour * (85-77) ^{0}C*1,16 $\frac{kW*h}{T*°C}$ =1113,6kW

Throughout the station:

∑ Q=18*1113,6=20044,8 кW=20 MW

20 MW of heat is lost with cooling water. To use this heat, the surface of the heat exchanger is calculated

F= Q*10³/K* Δt_{av}= $\frac{1113,6*10^3}{2000*11,3}$ =50 m²

Average temperature difference

$$\Delta t_{av} = \frac{\Delta t_{big} - \Delta t_{small}}{\ln \frac{\Delta t_{big}}{\Delta t_{small}}} = \frac{17-7}{ln\frac{17}{7}} = \frac{10}{ln2{,}43} = 11{,}3℃$$

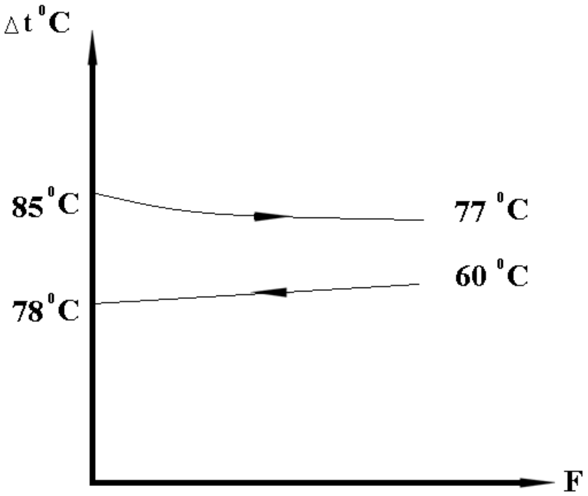

Figure 2: *Change in temperature difference across the surface of the heat exchanger*

Each unit will require a heat exchanger with a heating surface of 50 m². At the plant, the heat loss from exhaust gases is 99 MW, and with cooling water – 20 MW. Together, 119 MW of heat is lost at the station.

The calculation shows that for the climatic conditions of Baku, the heating load per 1000 people will require 780 kW of heat, and for hot water supply per 1,000 people will be needed 349 kW of heat [3]. Thus, to provide 1000 people with heating and hot water supply, 1129 kW or 1.129 MW of heat is needed. Then 99 MW of heat can be provided to $\frac{99\cdot1000}{1,029}$ = 96210 population with heat and hot water supply.

In such powerful power plants, additional electrical energy can be obtained from the heat of exhaust gases [4]. In industry, secondary energy resources are used to produce electrical energy. The most common method to generate electricity from secondary waste is the Rankine steam cycle (Fig. 3).

Here, secondary resources (exhaust gases coming from the engine) are used to produce steam in the recovery boiler. The resulting steam is then fed into a steam turbine. In a turbine, thermal steam is converted into mechanical energy, and in an electric generator, mechanical energy is converted into electrical energy. Also, in modular power plants exhaust gases 500^{0}C, along with thermal and electrical energy, can be used to produce cold (trigenation scheme) [5].

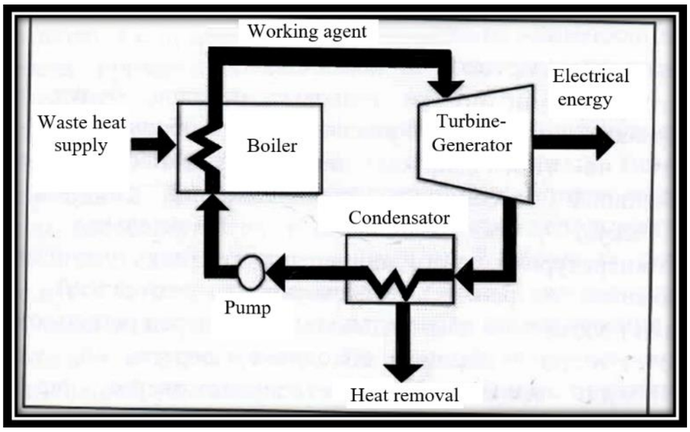

Figure 3: *Rankine cycle of a heat engine*

Currently, absorption refrigeration machines (ARMs) are widely used in industry. These machines require the following sources to operate:

1. Heat source.

A) Hot water with a temperature above 85^{0}C

B) Steam with a pressure of 0.1 MPa

B) Exhaust gases with temperatures above 230^{0}C

D) Natural gases

It can be seen that such sources are located in modular stations.

ARM consists of heat exchangers (generator, condenser, evaporator, absorber) in which on one side a LiBr solution or water (or water vapor) circulates under a vacuum, on the other side cooled water and cooling water circulate and a heating source in this case is water.

ARM operating principle:

The supplied heating source - hot water - heats the LiBr aqueous solution in the generator and generates water vapor from the solution, which in turn heats the cooling water in the condenser of the refrigeration machine and condenses to clean water. The resulting clean water then enters the evaporator (in a high vacuum state) and is dispersed over the copper pipes in the evaporator, taking heat from the cooled water, cooling it to 7^{0}C. The heated cooling water in the condenser, in turn, enters the cooling tower to discharge the resulting heat into the ARM. Water vapor from the evaporator enters the absorber, where it is absorbed by the concentrated solution coming from the generator. The resulting diluted solution is pumped back to the generator for heating, forming a cycle.

The main advantage of absorption plants in comparison with steam compressors is the low electricity consumption of up to 5-10 kW, for example, to produce 1 MW of cooled water, the ARM will consume 4.9 kW, then a freon cooler. It consumes about 250-300 kW.

ABHM have other advantages:

The use of cheaper energy (thermal) for drive compared to expensive electricity uses environmentally friendly refrigerant water. Service life is up to 30 years without major repairs. It has less noise and vibration. It is easier to operate, and has automatic control system it is used. In a power plant with an internal combustion engine.

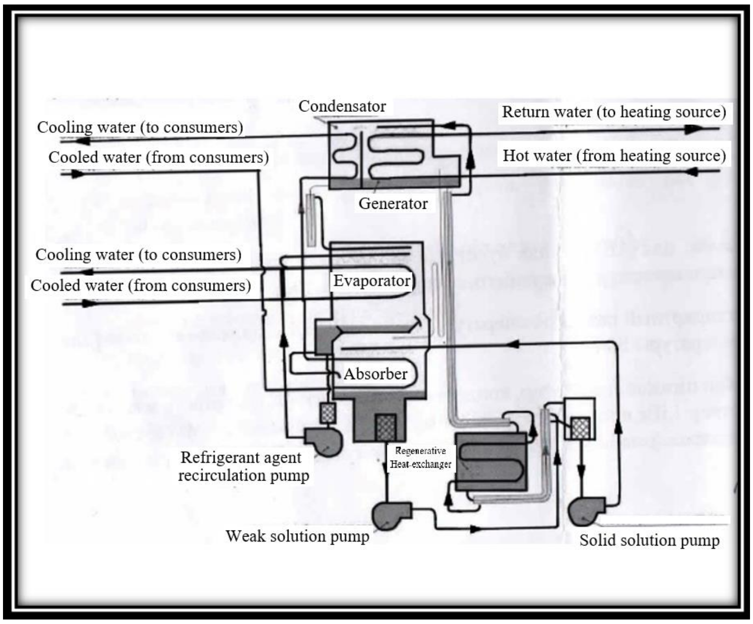

Figure 4: *Absorption lithium bromide refrigeration machines*

Power plants with combined production of heat, electricity, and cold (trigeneration plants) use fuel in the most efficient way and at the same time reduce carbon dioxide emissions. The overall efficiency of the station can exceed 90%. Trigeneration plants provide the ability to produce three important products - electricity, heating and cooling - using one power plant. Such stations can also be used for large facilities such as airports, shopping centers and other building complexes. This versatility does not compromise high reliability and excellent flexibility.

IV. Conclusions

1. The operation of modular power plants with a diesel engine with a capacity of 300 MW has been studied.
2. It was revealed that the loss of heat, fuel from exhaust gases is 99 MW, and with cooling water 20 MW.
3. Different schemes are proposed to use these losses, and by using heat at the station, additional electrical energy, steam, hot water and cold can be obtained.
4. The resulting thermal energy can provide 93,310 people with heat and hot water supply, the efficiency of the station increases by 16.8% and fuel savings will amount to 17.880 T/hour, the amount of emitted flue gases and environmental loads will decrease.
5. The introduction of trigeneration schemes increases the efficiency of the station, gives additional electrical energy received and steam generation, hot water and cold.

Abstract

When appointing an examination of the statute of limitations of a document, the courts traditionally take into account the expert's experience expressed in the years of expert activity, the timing and cost of the examination. However, any traditional approach tends to become obsolete. When assessing the quality of the choice of expert methods, one should first take into account the social damage that may arise as a result of receiving court decisions based on erroneous or unfair conclusions of an expert. And only secondarily evaluate the cost and timing of the examination.

Almost all such examinations in Russia are performed by gas chromatography. At the same time, there is already an awareness in the world that it is necessary to look for an alternative to this method. The number of refused expert opinions containing the wording "not possible" is close to 100%.

The reason for this is that, in addition to the limitations inherent in the chromatography method, an incorrect physicochemical model of the process, based more on everyday experience than on scientific knowledge, is proposed for data processing.

World science in this matter goes in two directions: attempts to improve chromatographic methods by means of complicated procedures of sample preparation, search for new components with long "evaporation" period, adaptation of sampling devices and extraction methods, etc, and develops new, non-chromatographic, physicochemical models of degradation of writing compositions.

The lag of domestic science has led to a sharp decline in the quality of methodological support for determining the age of documents and created the risk that a large number of legal disputes related to the examination of the age of a document will be resolved not in favor of the truth.

Meanwhile, the other extreme is unacceptable: a complete refusal to standardize forensic methods. Improves the quality of forensic methods, the development of a special system of standards or technical regulations is required. Alas, the norms of metrology, the courts are considered as secondary and insignificant, which contradicts world experience.

Keywords: statute of a document, dating of the document, limitations of a document

II. Introduction

When appointing an examination of the statute of limitations of a document, the courts traditionally take into account the expert's experience expressed in the years of expert activity, the timing and cost of the examination. However, any traditional approach tends to become obsolete.

When assessing the quality of the choice of expert methods, one should first take into account the social damage that may arise as a result of receiving court decisions based on erroneous or unfair conclusions of an expert. And only secondarily evaluate the cost and timing of the examination. The damage from expert errors can be many times greater than the procedural and monetary savings.

This phenomenon can be very clearly seen in the example of the modern Russian state of methodological support for examinations of the age of documents. Forensic examination of the prescription of a document (more precisely, the totality of its individual details) is a type of forensic technical examination of a document, along with handwriting examination and examination of document materials.

II. Discussion

Determining the limitation of the manufacture of props is one of the most difficult forensic technical examinations of documents. In addition to complexity, it is also one of the most popular, since, from the point of view of an unscrupulous participant in the process, "correcting" the date of production of a document is the easiest way to obtain irrefutable evidence in the Court [1]. Almost all such examinations in Russia are performed by gas chromatography. At the same time, there is already an awareness in the world that it is necessary to look for an alternative to this method. The method has many limitations and problems associated with hypersensitivity to interfering assay factors. The main limitation is the "depth of analysis" within 1-2 years ago. This is certainly not enough, since for most of the analyzed details a much larger age is declared. This can be clearly seen from the publications of the Russian Federal Center for Forensic Expertise [1-3], in which Russian Federal Center for Forensic Expertise specialists are trying to make improvements to the methodology as they gain experience in its application. But the approach based on the adaptation of experience does not lead to an improvement in the method, and the number of refused expert opinions containing the wording "not possible" is close to 100%. The situation is slightly better on the world expert platforms, but even there, the percentage of "failures" is approaching 70% [4].

The reason for this is that, in addition to the limitations inherent in the chromatography method, an incorrect physicochemical model of the process, based more on everyday experience than on scientific knowledge, is proposed for data processing. At the everyday level, you can very easily and clearly imagine how "high-boiling" components of writing materials evaporate. And by controlling this dynamics, you can calculate the "age" of the props. More often than others, for this purpose they try to use the dynamics of changes in the concentration of glycerol and 2-phenoxyethanol. Further, at the level of the same everyday experience, it is tempting to use the publicly available EXCEL program and get a "satisfactory" approximation of the evaporation dynamics by a function of the form:

$$C=Ax^{-b} \quad (1)$$

where x is the age of the stroke; the values of coefficient A and exponent b are found as a result of the modeling procedure.

This simplistic approach contradicts some of the fundamentals of physical chemistry.

Table 1: *Some properties of individual analytes of writing materials [5, 6]*

Component	Boiling temperature (°C)	Equilibrium saturated vapor pressure at 20 °C (kPa)
2-phenoxyethanol	244	0,001
glycerol	290	0,0004 (50 °C)
water	100	0,31
ethanol	78	5,8

It can be seen from the table that both glycerol and 2-phenoxyethanol are not volatile liquids.

They have very high boiling points close to 300 °C and extremely low vapor pressures under normal conditions, which is easy to verify by comparing them with really volatile liquids: water and ethyl alcohol. Glycerol vapors begin to appear only when it is heated above 50 °C. At room temperature, glycerol does not evaporate. Consequently, the dynamics of the content of glycerol and 2-phenoxyethanol is not associated with their evaporation. Нужно искать иные причины, т.е. химические реакции, в результате которых компонент деградирует в составе материала письма. In this case, one should use the basic equation of chemical kinetics, the so-called "Arrhenius equation", similar to the models of foreign authors [7].

World science in this matter goes in two directions:

- attempts to improve chromatographic methods by means of complicated procedures of sample preparation, search for new components with long "evaporation" period, influence of paper sheet, adaptation of sampling devices and extraction methods, sample weight and desorption time, etc. [8-10].
- develops new, non-chromatographic, physicochemical models of degradation of writing compositions. As a rule, they are based on spectroscopy methods using modern mathematical methods for processing measurement results [11]. There is undoubtedly progress in this direction, but the final goal is still far away.

Unfortunately, domestic science has not been involved in the world process for a long time. Fundamental research in this area has not been conducted since the end of the last century (the accumulation of experience in the use of a single technique cannot be attributed to the scientific process). Periodic publications of the experience accumulated in the Russian Federal Center for Forensic Expertise do not affect the fundamental basis of the method. The overwhelming majority of experts have the illusion that there is and cannot be an alternative to gas chromatography in the version of the 80-90s of the twentieth century. Unfortunately, this turned out to be a favorable ground for the emergence of entire groups of non-state "pseudo-experts" who, knowing the weaknesses of chromatographic analysis, undertake to carry out any examinations of the prescription of a document by fitting to a predetermined result. Only in December-January 2023-2024, the Courts of St. Petersburg and the Leningrad Region considered 5 Cases containing "research by the Expert" Mr. I.N.P., where the chromatographic method "established" the age of documents dated 2005, 2012, 2013, 2017. Confidence in his impunity is based on the fact that there is no reference method of analysis. And such cases are not isolated.

The argumentation of reviewers pointing out to the Courts the obvious inconsistencies of such pseudo-expertises with the fundamental scientific basis of chromatography and physicochemical analysis, as a rule, does not find support in the Court. The argumentation of reviewers, as a rule, is based on fundamental arguments that are obscure to the Court, and unscrupulous experts - on personal experience and everyday ideas of the judges and lawyers. And argumentation, requiring fundamental special knowledge, is usually perceived as incomprehensible and alien to everyday perception.

Thus, the lag of domestic science has led to a sharp decline in the quality of methodological support for determining the age of documents and created the risk that a large number of legal disputes related to the examination of the age of a document will be resolved not in favor of the truth. In addition to material, economic and financial damage, which, in theory, can be calculated, there is significant social damage from the fact that a "gap" has appeared in the country's judicial system that allows the Courts to be misled in the interests of one of the parties. This undermines confidence in the judicial system as a whole. This trend has long worried the qualified expert community. Most often, the problem is proposed to be solved by creating professional departmental councils, and commissions consisting of trusted specialists who will weed out unscrupulous experts and monitor the scientific validity of expert research. However, this measure will not have the desired effect if the members of such councils do not have the necessary amount of fundamental knowledge, but will be guided only by personal experience of using a limited number of methods. Therefore, structures authorized by the government of the Russian Federation, primarily the Academy of Sciences of the Russian Federation (Resolution of the Government of the Russian Federation of December 30, 2018 No. 1781 "On the implementation of scientific and scientific-methodological management of scientific and scientific-technical activities of scientific organizations and educational organizations of higher education, as well as examination of scientific and scientific-technical results obtained by these organizations, and on amendments to certain acts of the Government of the Russian Federation") and the Federal Agency for Technical Regulation and Metrology (Rosstandart) (Federal Law of June 26, 2008 No. 102 "On Ensuring the Uniformity of Measurements"). To assess the qualifications of an expert, it is also advisable to attract information from the database of the Russian Science Foundation eLIBRARY.RU (https://elibrary.ru/elibrary_about.asp), which gives a statistical assessment of the scientific qualifications of all specialists of the Russian Federation.

The scientific validity of expert methods is inseparable from the requirements of their reasonable standardization to the extent necessary to prevent improvisations of unscrupulous experts. The basics of national standardization are described in No. 184 "On Technical Regulation". National standards and all-Russian classifiers of technical, economic and social information, as well as control over the implementation of the Federal Law of June 26, 2008 No. 102 "On ensuring the uniformity of measurements" are under the jurisdiction of Rosstandart. Unfortunately, forensic activities are not included in the list of areas of activity subject to mandatory standardization.

E.R. Rossinskaya points out that: "The process of expert research includes both standardized components and components that determine the action of a forensic expert approximately, in general terms. The methodology always contains rules and recommendations on the key points that determine the research design. No method can provide for the entire content of a particular study. Therefore, creative components are usually present in every expert study" [12, p. 15-16]. This indisputable statement, however, gives rise to unscrupulous experts to "justify" the rejection of metrology requirements and create arbitrary self-invented methods, without caring about their scientific validity, which does not allow the introduction of standardization in the forensic field in full.

Meanwhile, the other extreme is unacceptable: a complete refusal to standardize forensic methods. o improve the quality of forensic methods, the development of a special system of standards or technical regulations is required. The technical regulations of expert research should include unifying requirements that ensure the general scientific and metrological reliability of research, as well as procedural requirements. Standardization and unification of forensic technical examination of documents should, first of all, relate to methods of preparing objects for research, storage, sampling and transportation, and, necessarily, metrological support. Alas, the norms of metrology, the courts are considered as secondary and insignificant, which contradicts world experience.

B Importance should be given to unification [13] - establishing the optimal number of standard operations, primarily of a procedural nature. All this work should be carried out taking into account the fact that when improving the quality of forensic technical examination of documents, society faces a contradictory but feasible task: standardization and unification while maintaining the freedom of the expert in the choice of methods and means of examination, according to Federal Law of May 31, 2001 No. 73 "On state forensic activity in the Russian Federation".

It should also be mentioned about the organoleptic group of methods, which, paradoxically, also play, in the future, an important role in improving the quality of forensic methods for determining the age of a document. This group of methods, by analogy, in relation to STED, can include "expert experience". This method cannot be completely excluded from consideration, although, as mentioned above, its absolutization, which is practiced by the judicial authorities, is more harmful than beneficial to improving the quality of methods. The objectivity of the organoleptic method depends on the qualifications, experience and abilities of the persons conducting the examination. This should be added (in relation to expert activity) the level of cognitive abilities of the expert. This group of methods can be used in commodity science to determine the quality of products, the use of which is associated with emotional effects on the consumer. Moral satisfaction from the fact of establishing justice in a judicial dispute can also be attributed to emotional reactions.

Meanwhile, world science is actively engaged in the problem of quantitative registration, objectification and elimination of subjectivity of criteria for organoleptic "experience".

It should be taken into account that a scientific direction has already emerged in this area, replacing the organoleptic subjective perception of the properties of materials with an instrumental one. We are talking about a group of technologies from the "electronic nose and electronic tongue" family. Electronic language technology, consisting of non-selective sensors, is a quasi-organoleptic method for representing the composition of chemical mixtures. An electronic tongue (nose) is a package of sensors, preferably miniature ones, each of which cannot have high levels of sensitivity and selectivity for the components being measured, but the cumulative signal of such families of sensors carries additional information about the structure and properties of the system, which cannot be obtained using each sensor separately.

The sensor package data is processed digitally and visualized as clusters of values on the coordinate plane of the selected components. The aggregate signal forms a visualized image of the system. Such technologies are also called "multisensory" [14]. This concept, imitating the human organs of touch, was implemented in the development of the already mentioned analytical tools "electronic nose" and "electronic language" [15-17], which were introduced into use in 1995 as a result of joint Russian-Italian developments.

The electronic language proposed in 1995 is already positioned as a sensor used to analyze any solution consisting of a complex set of components using a package of non-specific chemical sensors and image recognition [18-20]. For this electronic language, a new method of mathematical processing of the cumulative signal of groups of sensors using chemometric analysis was used. The obtained result could be easily visualized in the form of a 2D or 3D graphical model in the selected coordinate system. That is, in this field there is a symbiosis of the visual image, digital model and verbal description of the composition of the system. This greatly simplifies a number of analytical and expert tasks, as the visual image often simplifies verbal descriptions. In addition, a set of digital and visual data allows you to simulate the next stage of the human nervous system: the processing of an array of information by the brain, which is performed by software of the highest level. And then move on to sending commands to actuators and devices.

Chemometrics is a synthetic discipline located at the intersection of chemistry and mathematics. It allows you to implement complex data processing algorithms, in particular, the results of multidimensional and multifactorial experiments. The following methods are widely known in chemometrics: ANN (artificial neural network), DASCO (discrete analysis with short covariance matrix), INLR (implicit nonlinear latent regression), PARAFAC (parallel factor analysis), PAT (process analytical testing), PCA (principal analysis components), PCR (principal component regression), PLS (projection to latent structure), etc.

The most commonly used method of mathematical processing of electronic signals of the electronic tongue and electronic nose is the chemometric method of the principal components of PCA.

In turn, with the development of chemometrics, manufacturers of measuring instruments began to actively create equipment capable of measuring in the form of multidimensional data sets, rather than individual digital files or values [21].

Chemometric methods are already being introduced into forensic practice abroad. For example, in a forensic environmental examination [22]. An attempt has been made to apply it to the forensic technical examination of documents [23 – 25]. For this purpose dates of actual execution of document details are transformed into figures of spatial clusters on plane of coordinates of selected components of value matrices.

In the absence of such a presentation, specialists and experts would be faced with the difficult problem of verbally describing the results obtained for unprepared listeners. Demonstration of a visual picture of chemometric clusters, for example, during a court hearing, according to the plan, will help the judge understand the logic of the expert who made the conclusion based on the measurement results. Unfortunately, legal proceedings have not yet adapted this form of argumentation and prefer to rely on formalized verbal images and concepts, but we believe that we are talking about the near future, since scientific and technological progress will force the parties to the process to master this "language". We deliberately focused on this group of methods in such detail, since the use of a chemometric apparatus for the purpose of establishing the statute of limitations of a document in order to improve the quality of methods will actively develop in world science in the coming years in those areas of forensic examination where the main role, so far, is played by the experience and subjective opinion of the expert.

III. Conclusion

Summing up, it should be noted that the state of fundamental science in the field of dating documents in the Russian Federation is characterized by a set of problems. The necessary scientific research in this area is not carried out. In non-state expertise, there are entire groups of unscrupulous specialists who carry out conclusions by adjusting to a predetermined result. They argue their unreliable results with understandable at the household level, but not at all with scientific arguments. Legal proceedings are not yet ready for modern natural science and technical argumentation. Very often, the Court and the legal profession prefer to rely on concepts from the field of personal and everyday experience. An important task of improving the quality of forensic research is the mastery by the Judicial and Lawyer Corps of the language of fundamental scientific concepts and modern methods of mathematical processing of the results of expert research. Digital visualization of the results of expert research can provide significant assistance in this matter.

Acknowledgment

The work was carried out with the support of the Russian Science Foundation, Agreement No. 23-23-00365.

Abstract

The Republic of Azerbaijan is an oil and industrial country rich in natural resources. Determining and analyzing the activity of natural radionuclides in nature, studying the physical essence and mechanism of action of oil and gas deposits, radioactive aerosols in the environment are among the most urgent issues of the day.

It is important to study the physical nature and mechanism of action of radioactive aerosols generated in the environment in oil and gas extraction areas. The indicated radioactive substances show themselves as sources of α, β, γ - radiation, and their organotrope entering the living organism leads to undesirable pathology by having a bilateral, that is, synergistic effect. It is very important to investigate the individual and cumulative effects of these harmful effects.

Keywords: oil and gas deposits, natural radionuclides, radiation source, environment, harmful effects, radioactive substances, econometric evaluation

I. Introduction

The growing demand for oil and gas in the world economy has created conditions for increasing oil and gas production. As a result, the volume of radon gas generated during oil and gas refining has increased. Although global gas consumption in 2019 was lower than in 2018 (+2.6%), this growth continued (record year + 5.1%). Despite a 3.1% increase in natural gas demand in 2019 in the United States, the world's largest gas consumer with the emergence of new gas-fired power plants, gas prices have fallen. Growth by sector was uneven. Thus, although it was 7% in the energy sector, there no significant change in the utilities, trade and industry sectors [1].

II. Methods

In China, the increase in gas consumption has halved (+ 8.6%) due to the slowdown in economic growth and the easing of the policy of replacing coal with gas. China ranks 24% of global growth, ranking second in the world in terms of demand growth (+ 8.6%).

Consumption in the EU increased by + 3.1% due to improved demand in natural gas production countrie such as Spain, Germany and Italy, as well as Russia, Australia, Iran, Algeria and Egypt [1].

In Asia, the decline continues in Japan and South Korea due to declining demand in the energy sector (declining electricity consumption and increasing competition from nuclear and RES power plants). [2]

In Latin America, gas consumption remains stable; Brazil and Argentina saw a slight decline, while Mexic saw a 4.4% increase. Radon emissions have continued to rise in coal- and hydrocarbon-producing countries such as Russia, Australia, Iran, South Africa and Algeria. The following graph provides information on radon gas emissions in the CIS and AR [3].

As can be seen from the picture data the dynamics of radon emissions in 2000-2019, mainly in the CIS countries in 2002-2008, including the Republic of Azerbaijan, increased and in 2008-2010 this increase was observed in Azerbaijan with a decrease.

III. Results

In 2011-2016, the volume of radon emissions increased in Azerbaijan. Thus, compared to 2011, the volume of radon emissions in Azerbaijan increased by 18.9% to 33.3 thousand tons, and in the CIS countries decreased by 7.4% in the same period and amounted to 2300 thousand tons. In 2019-2022, this figure increased in the CIS and Azerbaijan.

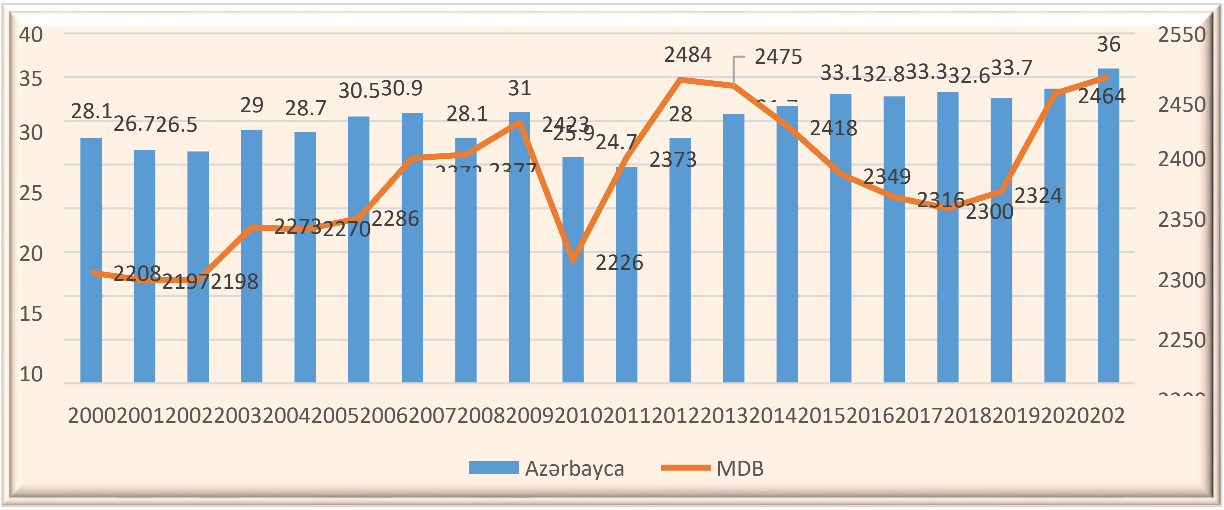

Figure 1: *Dynamics of radon gas emissions in the CIS and the Republic of Azerbaijan for 2000-2022, thousand tons*

China ranks first in the world in terms of radon emissions. The volume of radon emissions in this country at that time was 11,535,200 tons. The top ten includes China, the United States, India, the Russian Federation, Japan, Germany, Iran, South Korea, Indonesia and Saudi Arabia. Azerbaijan ranks 66th in the world in terms of radon emissions (36.0 thousand tons) [4].

The volume of CO_2 emissions in the Republic of Azerbaijan was higher during the former USSR. This can be seen more clearly in the chart below [5].

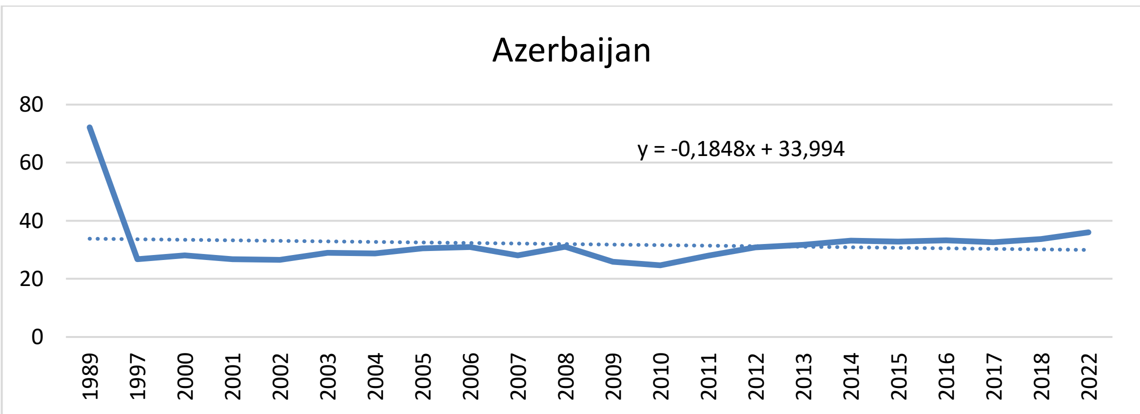

Figure 2: *Dynamics of radon gas emissions in the Republic of Azerbaijan for 1970-2022, thousand tons*

As can be seen from the data in the table, the volume of radon emissions increased to the peak in the Republic of Azerbaijan in 1970-1989. Thus, in 1989, this figure was 72.2 thousand tons compared to 1970.This means an increase of 2.23 times. As can be seen from the trend model, which shows the dependence of the volume of radon emissions in the Republic of Azerbaijan on the time factor, the time dependence is weak in terms of the correlation coefficient [1].

Increasing the amount of radon waste has a negative impact on human health by increasing the amount of waste per capita. From this point of view, one of the most important issues is the interaction of the volume of radon emissions in the Republic of Azerbaijan with radon emissions per capita. The chart below shows this information [6].

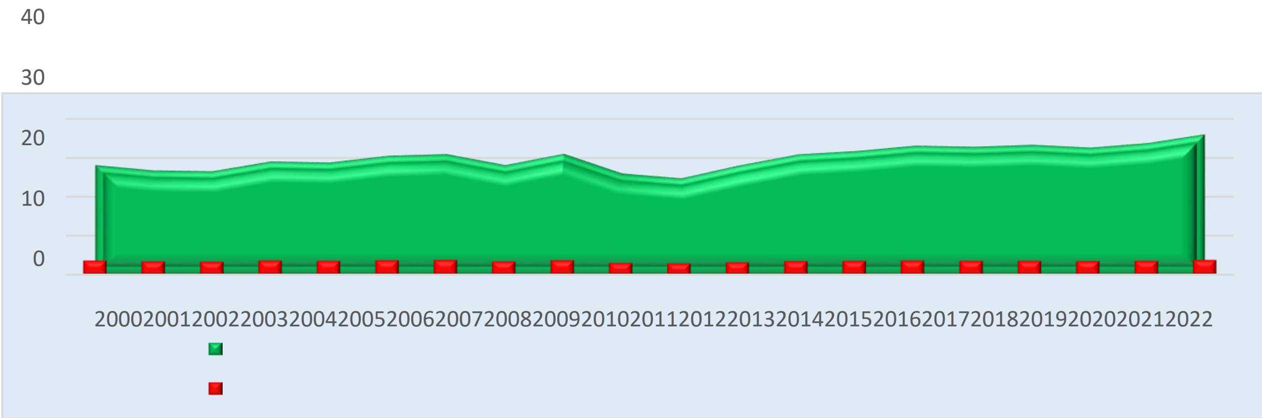

Figure 3: *Dynamics of radon gas emissions in the Republic of Azerbaijan for 1970-2022, thousand tons*

The impact of increasing radon emissions on per capita radon emissions can be explored.

Many ready-made mathematical software packages, including EViews, MatLab, MS Excel, MathCad, etc., are used to conduct regression analysis of the dependence of radon emissions per capita on the increase in radon emissions in the Republic of Azerbaijan [1]. It should be noted that the Eviews software package is more universal for the purpose of regression analysis, so using this software package, we obtain the following result based on the data in Fig. 3 above.

As can be seen from the Eviews application software package, there is an average correlation between the variables Y and X, expressed by the model Y = 0.0535 * X +1.726 (R2 = 0.524850). Thus, the degree of dependence between the indicators on the Cheddock scale, the fact that the quantitative value of the density of the connection is in the range of 0.3-0.5, show that the quality characteristic of the strength of the connection dependence is average [7], [2].

Based on this correlation equation, it can be concluded that the increase in the volume of radon emissions in the Republic of Azerbaijan is characterized by a 1.73 increase in radon gas per capita.

As can be seen, model (1) is statistically significant according to the table based on the EViews application software package. This significance is primarily explained by the fact that the coefficient of the free variable X, the free limit C, is higher than their standard errors.

Since it is important to check the adequacy of the established model, this adequacy can be determined using the F-Fisher criterion as one of the traditional methods. Expressing the regression equation as a whole (2) F-Fisher criterion to test the statistical significance of the model should be compared with the value of *F*figure (a; m; n - m - 1) [2]. Table 2 showing the results of the Eviews software package according to F- statistics (Fisher's criterion) = 19.88 .If we define the value of the table F in EXCEL using the formula *F*figure (a; m; n - m - 1)= F (0,05; 1; 18) = 4,41

When the F-Fisher criterion is compared with the value of *F* figure (a; m; n - m - 1), it appears that the F-Fisher criterion is>*F*figure (19,88> 4,41). The regression equation as a whole is statistically significant [2]. This means the adequacy of the established model (1).

Source. The Eviews application was developed by the author based on the software package.

The result of autocorrelation in the model can be determined based on the Darbon-Watson statistics in Table 3.1, obtained from the EViews application software package. As can be seen from the table, DW is equal to 0.927.In this case,

For 4 observational variables m = 1 and n = 20 observations at the significance level α = 0.05, the Darbon-Watson crisis points will be as follows [2].

$$d_l=0,902, \qquad d_u=1,118$$

$$d_l=0,902<DW=0,927<d_u=1,118 \tag{1}$$

As there is no conclusion on the existence of autocorrelation . [2].

dl = 0.902 <DW = 0.927 <du = 1.118 (3.1)

The regression equation as a whole is statistically significant and the constructed Y = 0.0535 * X +1.726 model is adequate.

Prices for radon gas per capita in the Republic of Azerbaijan and standard errors, found by the regression equation obtained on the basis of the Eviews application software package, as well as a number of characteristics of the use of the equation for forecasting purposes are shown in the graph below.

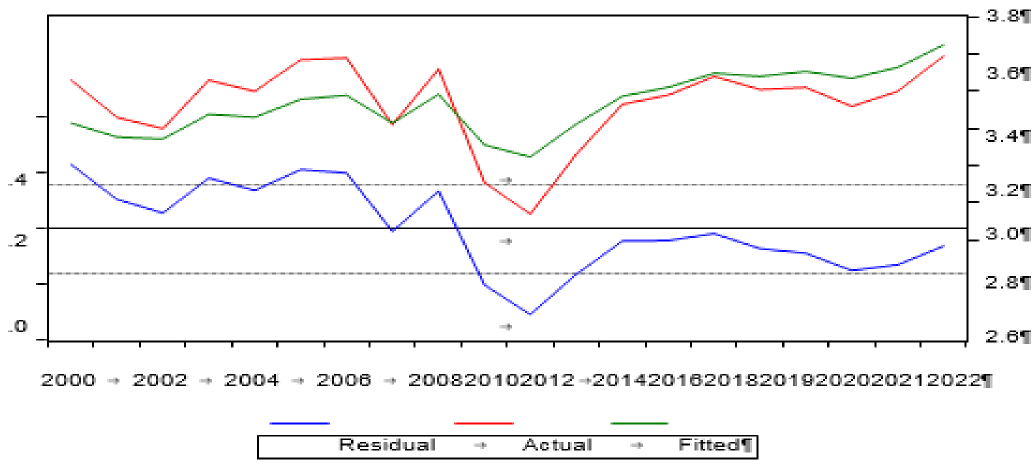

Figure 4: *Prices of radon gas per capita in the Republic of Azerbaijan by years, standard errors, characteristics for forecasting [8],[9].*

Using the graph, it is possible to determine the expected forecast prices for radon gas per capita in the Republic of Azerbaijan. Evaluation the impact of the increase in radon gas emissions during oil and gas refining in the Republic of Azerbaijan on the level of radon gas per capita by elasticity coefficient is also an important issue.

As a result of the study, by calculating the coefficient of elasticity for the linear regression equation above the degree of influence of the relationship between these indicators can be expressed as a percentage (1).It should be noted that the coefficient of elasticity is the percentage increase in the dependent variable due to a 1% increase in the free variable x included in the model or decrease is calculated according to the following formula [2].

$$E_{CO^2} = \frac{a_1 x_1}{y} \quad (2)$$

Here, αi are the coefficients of the above contact equation. $\bar{x}$ is the calculated average of CO_2 emissions for the studied periods, $\bar{y}$ is the calculated average of the level of radon gas per capita in the Republic of Azerbaijan for the studied periods. The elasticity coefficients calculated on the basis of these indicators will be as follows for the built model.

$$E_{CO^2} = \frac{a_1 x_1}{y} = \frac{0.0535 \times 30.105}{3.3355} = 0.482871 \quad (3)$$

Calculations show that a 1% increase in radon gas emissions in the Republic of Azerbaijan leads to a 0.483% increase in the level of radon gas per capita in the Republic of Azerbaijan.

If we establish a correlation-regression relationship between the volume of radon gas emissions in the Republic of Azerbaijan and the level of radon gas per capita in the Republic of Azerbaijan in MS Excel, we get the following result.

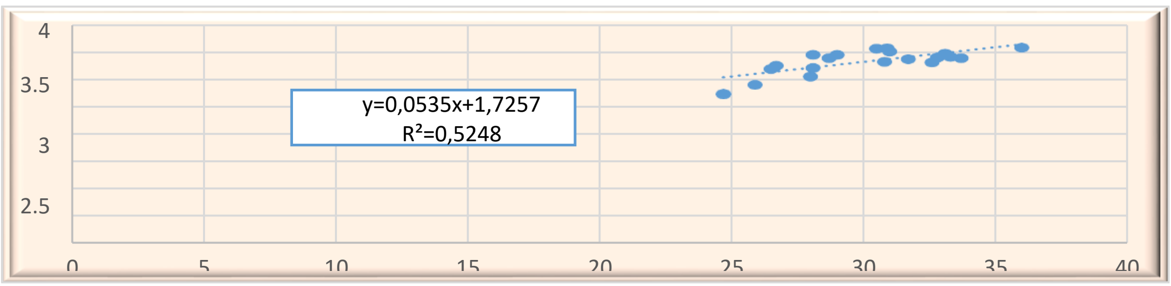

Figure 5: *Correlation-regression relationship between the volume of radon gas emissions in the Republic of Azerbaijan and the level of radon gas per capita [8]*

The correlogram of radon gas emissions of oil and gas refining in the Republic of Azerbaijan with the level of radon gas per capita in the Republic of Azerbaijan according to the Eviews software package will be as follows.

Table 2: *Oil and gas processing with per capita radon gas levels suspension of radon gas waste generated during*

The Eviews application was developed by the author based on the software package.

The linear coefficient of double correlation is calculated to estimate the density of the relationship between the studied indicators. This ratio is determined according to the following formula [2] [10].

IV. Discussion

Value of the coefficient [-1; 1] varies in the range. The closeness of the rxy-coefficient to the unit indicates that there is a close correlation between these indicators. The fact that $rxy = 0$ indicates that there is no linear dependence.

Although the ratio is zero and there is no linear relationship between the subjects, there may be a nonlinear relationship. The degree of dependence between the indicators is determined mainly by the Cheddock scale. The linear coefficient of double correlation also determines the direction of cause and effect. Thus, if $rxy> 0$, there is a direct relationship between the indicators. That is, as the causal factor (x) increases, so does the value of the outcome indicator (y).

If $rxy<0$, then there is a feedback between the indicators.is, as the cause factor (x) increases, the value of the outcome indicator (y) decreases. The CORREL statistical function is used to determine the linear coefficient of double correlation based on the Eviews application software package.

According to the table, R2 = 0.525 means that the corresponding regression equation is explained by 52.5% of the variance results, and 47.5% by the influence of other factors.

The dynamics of the Fitted and Actual values, as well as the residuals between them, according to the regression equation of the built-in model (2) and the Eviews application software package, are given in the graph below [2].

There is a mean correlation expressed by the linear regression equation Y = 0.0535 * X +1.726.

Abstract

The reliability of the system for collecting products from oil, gas and gas condensate fields directly depends on the condition of the well flow lines. Many years of experience in the exploitation of offshore fields in the Azerbaijani sector of the Caspian Sea shows that various kinds of complications arise in the flow lines of wells associated with salt deposits, asphalt base, tarry oil and paraffin deposits, fluid accumulation, pressure pulsations, etc.

The listed complications lead to the formation of blockages in the flow lines, an increase in the mechanical load on the equipment and, ultimately, to a decrease in the productivity of lines and wells, up to the point of stopping their operation. Work to restore these lines takes quite a long time and requires significant costs.

Reducing technological risks in the operation of well flow lines is closely related to diagnosing their condition. But planned diagnostic work involving forces and equipment often in practice reveals complications at a late stage of their development and engineering decisions are made to shut down wells and restore lines.

In connection with the above, the issues of diagnosing complications at an early stage of their formation acquire current and practical importance. Timely cleaning of flow lines and regulation of operating conditions of production wells, such as the selection of an adequate wellhead pressure regime and other technological solutions, can prevent a negative scenario for the development of complications. In turn, for early diagnosis of complications it is necessary to find a diagnostic criterion. determining the beginning of their formation. Due to the fact that the main flow parameters at the metering nodes are continuously recorded in real time, it would be advisable to develop an appropriate diagnostic criterion based on the results of studying the dynamics of time series for the main indicators of flow lines.

For this purpose, in this work, flow lines of wells in the Bulla-Deniz field (Azerbaijan) were studied. The main indicators for the studied lines were length and diameter, pressure at the beginning and end of the line, gas factor and line productivity. Based on these indicators, data processing was carried out and corresponding statistical estimates were obtained.

The results of the analysis revealed a stable correlation between gas factor indicators and flow line performance. It was established that a sharp decrease in line productivity with an increase in the gas factor manifested itself in wells in which restoration work was carried out due to complications that arose. This makes it possible to use this behavior of the curves of the dependence of flow line productivity on the gas factor as a criterion for diagnosing complications at an early stage of their formation.

The results of this research can be recommended for use in the operation of a system for collecting and transporting oil and gas field products.

Keywords: flow lines, risk analysis, diagnosis of complications, gas factor, line productivity

I. Introduction

Well flow lines, as an element of the gas and oil collection network, are pipelines originating at the wellhead and ending at the entrance to group metering installations [1]. Many years of operating experience show that various kinds of complications arise in flow lines, the elimination of which requires stopping the operation of wells and carrying out repair work, accompanied by significant downtime and, as a consequence, material and labor costs.

In work [2], using the example of Russian fields, it is shown that the accumulation of liquid, especially at the late stage of development, leads to a number of complications both in flow lines and in the operation of process equipment at the collection point. Among them, one can highlight an increase in hydraulic resistance, the observation of volley releases of liquid into separation units, pressure pulsations and the formation of hydrate plugs with a decrease in temperature in winter. The authors here also propose, in order to reduce the risk of liquid accumulation, optimal regulation of gas extraction modes, which, ultimately, should also significantly increase the operating efficiency of separation units.

The authors in another work [3] list asphalt base oil, tarry oil and paraffin deposits, the formation of emulsions, hydrates, and inorganic salts as the main factors leading to complications in field pipelines. The researchers in this work brought some clarity to the conditions and mechanism of formation of the above factors and listed existing methods for reducing the risk of their formation.

Technological risks associated with the formation of hydrate plugs and the loss of paraffin deposits in pipeline lines have been studied in detail in studies [4]. Here, the authors proposed a probabilistic model for assessing the above risks in pipelines transporting oil and gas, tested it on real field data and showed fairly good performance.

In offshore oil and gas production, flow lines are connected to a subsea pipeline that transports well production to onshore collection and treatment facilities. In this regard, the above complications in the operation of flow lines lead to potential hazards in the operation of underwater pipelines, which were analyzed in detail for the conditions of the Caspian Sea in [5].

Reducing risks in the operation of well flow lines and, in general, subsea pipelines, field process pipelines and other pipeline communications is directly related to the ability to diagnose their condition. It is important to note here that quite often, diagnostic work begins to be carried out after complications have arisen in their work and work to restore them requires significant costs. Therefore, issues of early diagnosis, that is, timely detection of the onset of complications, have always been of scientific and practical interest and remain relevant today.

For example, in article [6] the use of fractal analysis for diagnosing liquid inclusions in gas flows in field gas pipelines is justified. Based on field data, flow characteristics were constructed for the flow lines of selected wells and the corresponding values of the fractal dimension were obtained using the coating method. A stable correlation has been established between changes in fractal dimension and the presence of liquid inclusions in gas flows. The presence of such a stable connection was also confirmed by the results of studies conducted in [7].

Thus, a change in the fractal measure of flow characteristics curves seems to be a fairly effective analytical criterion for early diagnosis of complications in the operation of flow lines of wells, in particular the accumulation of the liquid phase in them.

II. Methods

As the object of research 23 flow lines of the "Bulla-Deniz" field (Azerbaijan) have been taken and dynamics of the change of average values of the following indices have been analyzed: oil consumption, gas consumption, pressure at the beginning and end of the line, gas factor, average temperature of the flow and productivity of the flow line. All these indices are presented in the Table 1.

Studied lines were divided into two groups due to their productivity on the basis of hyperbolic value of distribution to reveal the flow lines in the operation of which complications occurred [8].

Table 1: *Values of operational parameters of the flow lines*

Flow lines	Diameter D, m	Length L, m	Rate of oil, q_{oil} ,t/day	Rate of gas q_{gas} , m^3/day	Pressure at the beginning P_1 , MPa	Pressure at the end P_2 , MPa	Gas factor q , m^3/t	Temperature t , °C	Ourput of line t/day/MPa

100	0,102	1200	310	53	4,4	2,1	170	55	134,8
84	0,102	1350	220	22	5,1	2,0	100	45	70,9
80	0,102	1250	255	65	4,0	1,8	254	53	115,3
32	0,102	1500	250	47	3,5	0,9	188	53	96,1
45	0,102	1650	225	20	4,7	1,2	88	59	64,3
85	0,102	1750	150	40	4,9	3,5	266	35	107,0
76	0,102	1750	140	38	5,9	4,5	271	29	100,0
39	0,102	1500	60	6	3,7	2,3	100	54	42,8
36	0,102	1400	180	25	4,4	2,8	140	32	112,5
105	0,102	1300	320	39	6,4	3,9	310	42	94,1
17	0,102	1300	230	57	6,0	3,5	250	40	92,0

Flow lines with output below 92 t/day/MPa refer to the first group and above 92 t/day/MPa were collected to the second group. After division into groups we proceeded with big probability that complications have occurred in the lines with small productivity. That's why flow lines have been separately taken on each group: № 9, 65, 43 and 122 — from the first group line; № 61, 57 and 48 — from the second group line. Samples on monthly indices of oil consumption; gas factor and line productivity have been prepared individually. These indices have been processed for establishing static relations between existing methods of data analysis.

III. Results and discussion

The results of data processing have revealed definite regularity in the behavior of the dependence curves of flow line productivity on the gas factor. Thus, for the flow lines of the second group where no complications were observed (lines N 61, 57 and 48) gas factor weakly influences oil consumption change at the same pressure drops. By the other words points plotted on the coordinates of flow line productivity ($q_{oil}/\Delta P$,t/day/MPa) and gas factor index (q) are located on the straight line rather accurately (Figure, a). As it is seen from the figure increase of gas factor index doesn't considerably influence flow line productivity decreases. Together with it, analysis of dependency of productivity on the gas factor index for flow lines of the group (lines 9, 62, 43 and 122), where complications were observed has revealed the following stable regularity. In these lines productivity considerably decreases by the increase of gas factor (Fig. 1). It can be explained by that due to the complications occurred in the lines, oil consumption decreases, part of the gas dissolves in the sediments and as a result productivity of flow lines reduces.

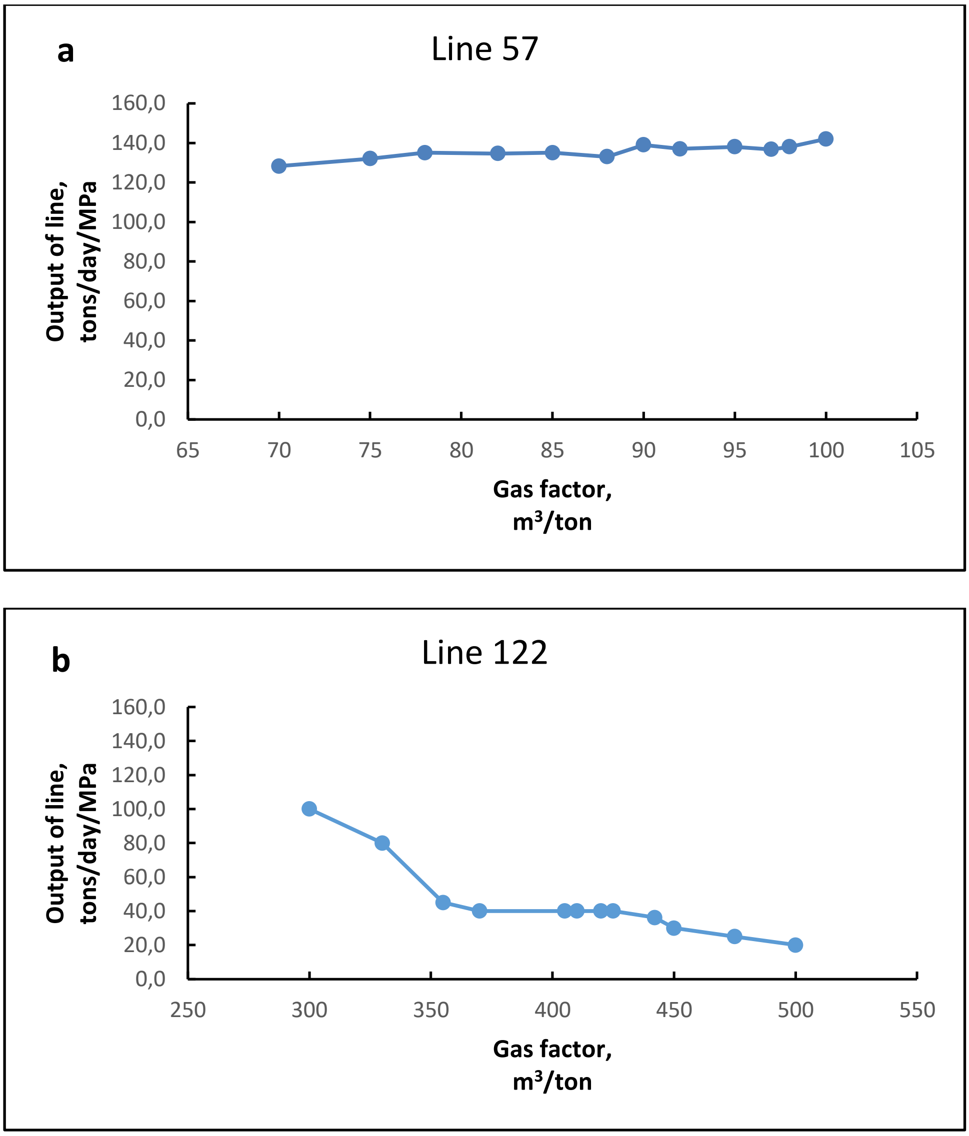

Figure 1: *The curves of the influence of the gas factor on the output of the flow lines*

The result of the carried out researches allow us to determine the following main conclusion that considerable decrease the productivity by gas factor increase is the diagnostic criterion for early revealing of the occurrence of complications in the flow lines and carrying out recovery works in time.

AUTOMATED CONTROL SYSTEM FOR THE SUPPLY OF LIQUID FUEL TO A TUBE FURNACE

Aygun Safarova, Elchin Melikov, Tamella Magerramova

•

Azerbaijan State Oil and Industry University
elchin03@mail.ru

Abstract

For optimal control of technological processes in explosion- and firehazardous industries, which include oil and gas refining, chemical and petrochemical objects, one of the main and pressing issues is the effective control of the liquid fuel supply to tube furnaces. To automatically regulate the output temperature of the raw materials supplied to the furnace on the liquid fuel line, an appropriate actuator is used. At the same time, gas fuel is continuously supplied to the tube furnace. The main reason for the intermittent supply of liquid fuel is that it is used as a feedstock for other technological installations It is known that feeding fuel into a tube furnace is unsafe for the technological process as a whole, that is, it is a process of a certain increased danger. This can lead to unwanted fires and explosions in the workplace. Therefore, to reduce some technical and technological risks, it is important to use liquid fuel with appropriate breaks, since the use of dry gas in a technological system poses a certain danger.

Keywords: technological process, liquid fuel, technological risk, tube furnace, control system, gas fuel

I. Introduction

Oil refining is a large-scale production, consisting of a large number of complex technological installations, which are complexes of many interconnected technological apparatuses [1-11]. One of such important and complex oil refining technological apparatuses is tube furnaces. Tube furnaces are used in the following oil refining installations: primary oil refining as part of Atmospheric Vacuum Tube installations; reforming; hydrocracking; viscosity breaking; delayed coking installation; isomerization; hydrogen production by steam reforming, etc. [12, 13].

It is known that tube furnace is a technological apparatus for heating a flow or carrying out a high-temperature chemical reaction due to the heat that is released during the combustion of organic fuel, that is, it is intended for heating hydrocarbon raw materials by open fire heating of tubular coil with gases in the combustion chamber from the combustion of liquid or gaseous fuel. After heating hydrocarbons in tube furnaces, they are subsequently sent to distillation columns to separate them into components (diesel fuel, heating oil, gasoline, etc.).

Thus, tube furnaces are used in any oil refinery and petrochemical plant in all major refining processes [14-17]. This is due to the fact that a tube furnace is the most cost-effective and efficient process for heating oil fractions.

Due to the lack of fuel gas produced in oil refineries, liquid fuel is also used to heat raw materials in process tube furnaces.

Combustion of liquid fuel in tube furnaces at oil refineries is ineffective from an economic and environmental point of view, since, on the one hand, environmental pollution by flue gases increases, and on the other hand, the possibility of using liquid fuel (fuel oil) as a raw material is reduced. Therefore, rational use and saving of liquid fuel is a very important and pressing problem in similar industries and is of great importance for the entire economy as a whole.

For this purpose, thorough research work was carried out in the field of the raw materials heating process entering the tube furnace in an oil refinery and the following shortcomings were identified:

1) the existing fuel network management system (processing of gaseous fuel, as well as its use) does not meet the requirements of modern automated operational control systems (there is no effective and optimal automated control system between production and relevant consumers);

2) since the total amount of fuel gas used in technological installations cannot provide the amount of fuel required to heat raw materials in tube furnaces, they also use liquid fuel along with dry gas. At the same time, to control the required temperature of the product at the outlet of the tube furnace, dry gas is continuously supplied to the technological system. It is important to note that when gas is supplied to the system, there is a possibility of an explosion and fire hazard in a tube furnace. This circumstance turn, can lead to certain technological and technical risks when heating the raw materials used. Thus, this affects the correct and efficient functioning of the automated control system as a whole.

In addition, it should be noted that in oil refineries regulate the temperature of the feedstock leaving the tube furnaces and select the gas fuel flow rate. On the other hand, adjusting the temperature of the raw material at the outlet of the tube furnace with gas flow leads to the fact that part of the dry gas is released into the flare line to equalize the pressure in the fuel network to a given value.

II. Development of an automated control system for the supply of liquid fuel to a tube furnace

From the factors mentioned above, it is clear that to eliminate the corresponding technological and technical risks arising in the gas and fuel technological network, it is necessary to create an automated control system for liquid fuel processing. At the same time, the automated control system for emergency situations must ensure that the following conditions are met:

- the pressure in the gas distribution point must be maintained constant (stable) according to the set point value;
- the discharge of dry gas from the gas distribution point to the flare line of the technological system should be minimized;
- the temperature of the raw materials at the outlet of the tube furnaces must be maintained constant (stable) in following the set point value.

An automated control system that meets the above requirements is presented in Fig. 1. When the gas pressure (position 5-1) coming from the gas distribution point increases, (position 5-2) and the pressure regulator (position 5-3) acts on the valve (position 5-4) located at the entrance to the tube furnace, according to a command received from the setting device, increasing its throughput.

In this case, the pressure of the gas supplied after the gas separator to the tube furnace (position 6-1) drops. In this case, to stabilize the pressure of the fuel gas supplied to the tube furnace according to the set point value, it acts on the secondary device (position 6-2), from there on the regulator (position 6-3), the control valve (position 6-4), increasing the capacity of this valve. In this case, the temperature of the raw material at the outlet of the tube furnace by the set point value is realized as follows.

Signals from thermocouples installed on the ridge wall and the outlet of the tubular furnace (position 1-1) and (position 2-1) are supplied, respectively, to temperature converters (position 1-2) and (position 2-2), and then they go to electric-pneumatic transducer (position 1-3) and (position 2-

3), and from them they are further sent to secondary devices (position 1-4) and (position 2-4).

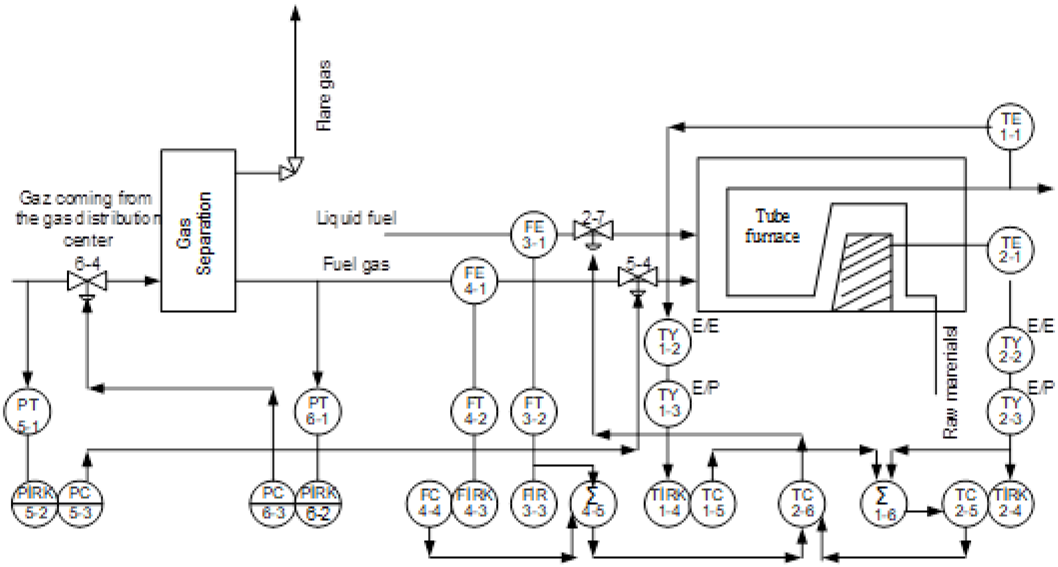

Figure 1: *Structural scheme of an automated system for the supply of liquid fuel to a tube furnace*

Having received a set point value from the output of the device (position 1-4), the controller signal (position 1-5) goes to the summator (position 1-6).

At the same time, the input of the summator (position 1-6) also receives a signal from the output of the electro-pneumatic transducer (position 2-3). At the same time, the output signal of the summator (position 1-6), as a variable value, is supplied to the temperature controller (position 2-5) by the set value coming from the secondary device (position 2-4).

The output signal of the temperature controller (position 2-5) is fed to the input of another temperature controller (position 2-6) as a set point value. The temperature controller input (position 2-6) receives signals from flow sensors (position 3-1) and (position 4-1) as variable values. The output signal of the temperature controller (position 2-5) is fed to the input of another temperature controller (position 2-6) as a set point value.

The temperature controller input (position 2-6) receives signals from flow sensors (position 3-1) and (position 4-1) as variable values. Pneumatic signals from local devices (position 3-2) and (position 4-2) are accumulated in the summator (position 4-5) and then the output signal of this summator in the variable value form is supplied to the input of the temperature controller (position 2-6). As a result, the temperature controller output (position 2-6) acts as a force on the control valve (position 2-7), reducing its flow capacity.

It should be noted that if the pressure in the gas distribution center drops below the set point value, the automated control system presented above has the opposite effect.

Let's look at a microprocessor system for controlling the process of heating raw materials in tube furnaces.

It is known that heating raw materials in tube furnaces during primary oil refining is a very complex heat engineering process, the correct implementation of which depends on the correct control of numerous technological parameters of the apparatus under study. Therefore, it is necessary to create a control system in tube furnaces that ensures stable maintenance of operating parameters under technological requirements. The structural scheme of such a system is presented in Fig. 2.

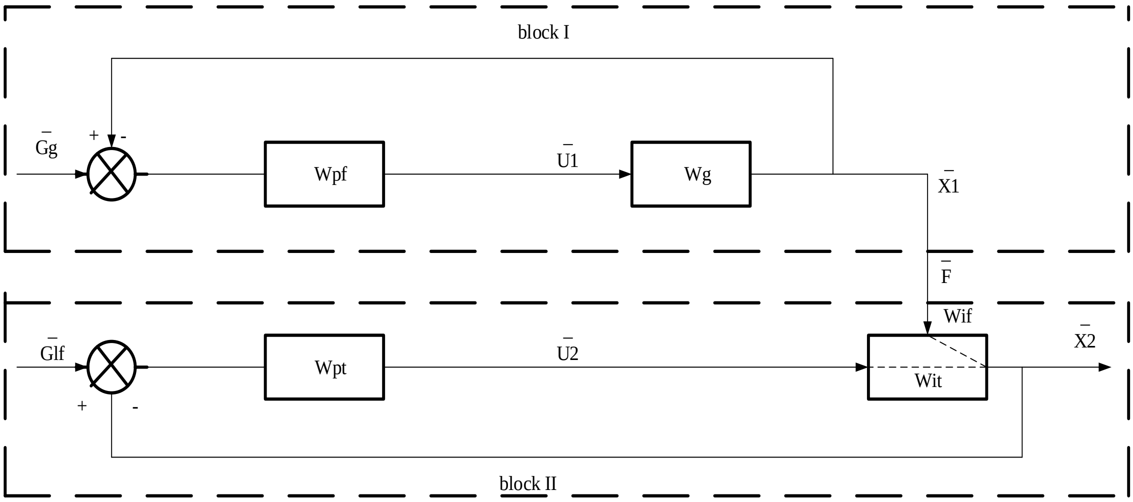

Figure 2: *The structural scheme of a microprocessor control system*

Here W_{pf} and W_{pt} are the diagonal matrices for the transfer functions of the multichannel flow and temperature controller, respectively. W_{if} and W_{it} – transfer functions matrices of the technological object for gas flow and between the temperature channels of the raw material at the tube furnace outlet. $\bar{G}_g$ and $\bar{G}_{lf}$ are vectors of set point values for gas and liquid fuel consumption. $\overline{X1}$ and $\overline{X2}$ are the vectors of output parameters (temperature). $\overline{U1}$ and $\overline{U2}$ are vectors of regulatory actions. As can be seen from Fig. 2, the control system consists of two control blocks – I and II. With the help of block I, the optimal gas fuel division between technological tube furnaces is realized, and with the help of block II, a constant (stable) temperature at the outlet of the tube furnaces is maintained. Analysis of this structural scheme shows that, on the one hand, a change in vector G1 along the direct channel has a disturbing effect on the output parameter $\overline{X1}$. On the other hand, since block I is powered by the collector, changing the regulator in it causes a change in the adjacent controlled parameter in the same block. Therefore, in technological tube furnaces, disturbing influences arising in the system for regulating mode parameters are transmitted not only through a direct channel but also through a transverse channel.

Therefore, to improve the quality of regulation, it is necessary to create an autonomous regulation system in block I and an invariant regulation system in block II, based on the above principles.

It is known that when controlling technological processes in oil refineries, not one, but several tube furnaces are used. Therefore, to correctly and effectively regulate the temperature at the outlet of tube furnaces, a combined computer control system has been created.

The structural scheme of the proposed combined computer control system is shown in Fig. 3. The system operates in the following order: changing the set point value of the regulator in accordance with the optimal price of fuel gas is carried out by the dispatcher (operator). But after converting the current values of regulating and disturbing influences into a direct current signal with a 4-5 mA strength, through the appropriate electronic type converters, they are supplied to the input of an analog-to-digital converter located in the control computer complex. The analog-to-digital converter, in turn, converts the analog signal into codes. After the analog-to-digital converter, the signal through the multi-channel control software module also determines the magnitude of the control action, and this signal is sent to the input of the digital-to-analog converter located in the computer. The direct current signal (4-20) mA, which appears at the output of the digital-to-analog converter, is converted through an electro-pneumatic converter into a pneumatic signal (0.2-1) kg/cm² and acts on certain actuators. Current technological parameter values characterizing the heating process raw materials in tube furnaces are displayed on the display screen, and the operator enters into dialogue with the control computer complex to complete the task.

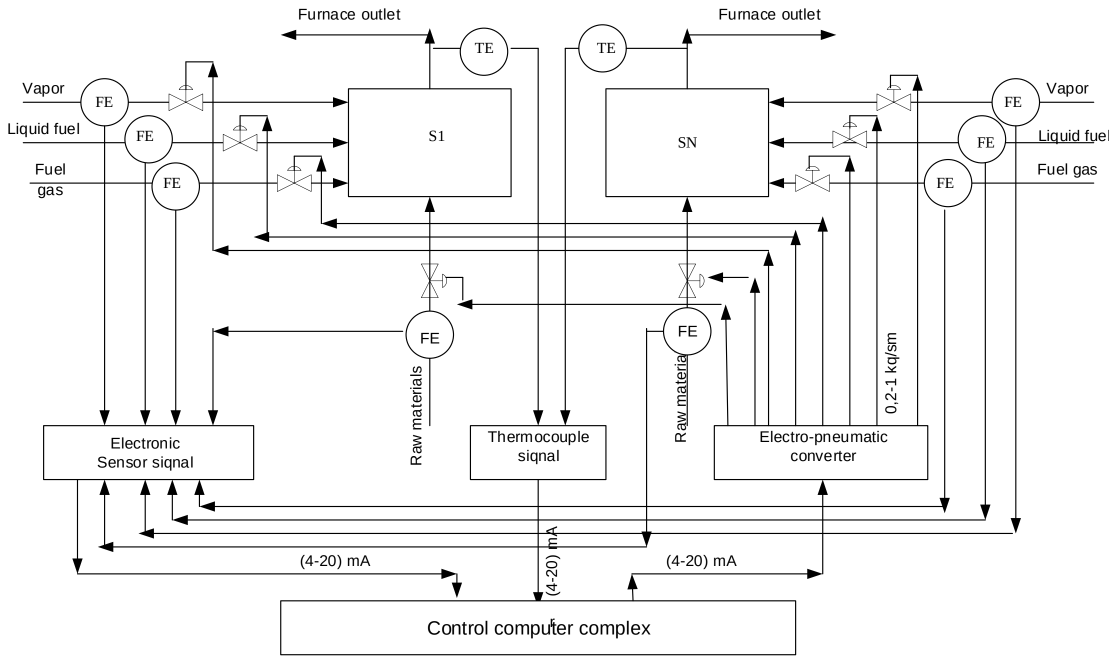

Figure 3: *Structural scheme of a combined computer control system*

III. Conclusion

An automated control system for the supply of liquid and gas fuel to a tube furnace has been developed. When supplying gas from a gas distribution center to a tube furnace, a system has been developed to regulate the flow and fuel gas pressure. To regulate the temperature of the raw material supplied to the tube furnace, which is important for the technological process, an actuator installed on the liquid fuel line is used.

Heating raw materials in a tube furnace is a complex process. In this process, stable preservation of the many mode parameter values must be ensured by the set point value. In this regard, the proposed microprocessor system for controlling the consumption of liquid and gaseous fuel, quality indicators, temperature, and pressure has been developed.

To maintain a stable temperature of the output raw material in tube furnaces, a control computer complex is proposed in a combined computer control system.

Thus, based on the above, various types of automated control systems have been developed to maintain the necessary and required temperature of the technological process under study.

Abstract

In the article, the solution of the issues of transportation of the produced product in the oil and gas extraction department occupies one of the main places. Pipelines belong to technological systems that represent fire-explosion dangerous objects with a complex structure capable of hydrate formation, erosion, ignition, explosion and environmental pollution. By reducing technological risks that may occur in underwater pipelines, it is possible to ensure technological and environmental safety at sea and protect marine bioresources. Risk analysis using statistical data can reveal the negative consequences of natural hazards and other external influences on the pipeline system.

Keywords: gas, hydrate, oil and gas extraction, pipelines, risk, hydrocarbon accumulation, gas condensate, paraffin, condensate

I. Introduction

Researches and field works should be carried out to improve the technological process and develop new scientific and technical proposals in order to reduce hydrate formation and other possible technological risks during the process of gathering and preparing gases produced from gas condensate deposits for transportation. These research works should be carried out in several directions [1,5]. It can be determined by studying the operation of separate devices of hydrocarbon gas collection and transport preparation units operating in the oil and gas extraction station. Reducing the risks of hydrate formation during exploitation in field conditions, choosing the optimal technological mode of operation for the collection and preparation of hydrocarbon gases for transportation and the selection of reagents with high efficiency during the process are important issues [2,4].

II. Research and analysis of results

It is known that both underground and surface gas pipelines are constantly exchanging heat with the environment. For this purpose, it is considered technically, technologically and economically efficient to develop, apply reagents in the technological process to reduce the risk of hydrate formation, drying of gas from water vapors, corrosion, salt and paraffin deposits in the gas hydrocarbon collection, preparation for transporting and transportation system. Taking these into account, it is appropriate to analyze and improve the technological processes applied in the oil and gas industry in recent years to reduce the operational costs incurred in the gas collection, preparation for transporting and transportation processes, prepare quality indicators in accordance with international standards, and to decrease the risks of hydrate formation that may occur.

Since the efficiency of low-pressure gas collection and transportation processes depends on the compliance of the equipment related to these processes with the requirements of relevant technologies, the operating modes of pipelines and compressor stations should be investigated.

The study of the influence of the low-pressure gas transportation pipelines on the indicators of the station until the reception of the compressor station is carried out on the following issues.

The indicators of the compressor station consist of its destination parameters. These parameters are related to the following factors:

- factors that have a positive or negative effect on the operation of the compressor units of the low-pressure gas pipelines before the station reception;
- factors that increase or decrease the gas permeability of low-pressure gas pipelines;
- ambient temperature and humidity affecting gas pipelines and compressors.

The main factors affecting the ability of low-pressure gas transmission pipelines to the compressor station reception: depend on the diameter of the pipeline, its length and the curves of the pipelines.

In order to study the gas permeability of the pipelines, the construction of each pipeline is determined, after recording its starting and ending points, important factors affecting the compressor station, increasing or decreasing its productivity are determined.

The construction of plugs and connecting devices installed at the beginning and end points of the pipeline and the opening and closing times cause changes in gas parameters (pressure, temperature, and quantity) and thus affect the indicators of the compressor station.

The results of the conducted research and field work showed that as a result of the change of thermodynamic parameters (P, T, Q, etc.) in the process of transporting natural and associated gases, the gas phase leaves the liquid phase (water + condensate + oil fractions + paraffin deposits, etc.) on the inner surface of the gas pipelines. This creates difficulties in its turn. Thus, the formation of hydrate in the system creates an emergency situation, in addition to reducing the productivity of gas pipelines, leading to the loss of large volumes of gas and condensate. Overcoming these difficulties requires additional operating and energy costs.

Taking these into account, it is appropriate to consider in advance and report the temperature regime of the area where the gas pipelines pass, depending on the season, in order to ensure the smooth transportation of low-pressure gases to the compressor station.

The results of the research and field works carried out in the DWF show that the development of new scientific and technical proposals to ensure the unimpeded transportation of low-pressure gases from deep sea foundations to the under-construction FCS (field compression stations) is one of the urgent issues of the day.

The results of the conducted field studies showed that in order to increase the efficiency of the gas lines between the DWF and clean the liquid phase (water + condensate) falling into the line, it is planned to release a ball in each line of the project. However, the results of field studies show that an additional force is needed to ensure the movement of the ball inside the pipeline.

It is known that since the pressure of the surrounding gases is too low, 0.15-0.20 MPa cannot ensure the internal movement of the ball in the pipeline and its cleaning from the liquid mixture. Taking these into account, it is more effective to increase the efficiency of low-pressure gas transportation by using a number of technologies, as low-pressure gas transportation lines pass through complex relief areas.

During the movement of the gas through the seabed pipes, the liquid contained in it separates and after a certain time passes, preventing the passage of the gas, it ensures the formation of hydrate. Although this problem has been tackled in various ways, its solution is still relevant. Let's look at finding the pressure needed to clean up liquid build-up and eliminate the risk of hydrate formation when transporting gas through a pipeline on the seabed. In the first option, let's look at the worst case, that is, when the pipes are completely filled with a liquid mixture.

If to assume that the fluid is incompressible, its equation of motion is as follows [3]

$$0 \le s \le \frac{\ell}{2} \qquad m\frac{dv}{dt} = P \cdot f - 2\pi R(\ell - s) \cdot \tau - \rho g s f \sin\phi \tag{1}$$

Here $\sin\phi = \frac{2H}{\ell}$, $m=\rho\pi R^2(\ell - s)$ is the mass of liquid; ρ - the density of the liquid; ℓ; R, f - the length of the pipe, the inner radius of the pipe, and the cross-sectional area, respectively, τ - the friction between the fluid and the inner surface of the pipe wall is the shear stress.

If to substitute the mass of liquid in expression (1), we get the following equation:

$$\rho\pi R^2(\ell - s)\frac{dv}{dt} = Pf - 2\pi R(\ell - s)\tau - \rho g s f \sin\phi \tag{2}$$

The relationship between the frictional stress and the average speed can be found as follows:

$$\tau = \mu v \tag{3}$$

μ - is the resistance coefficient between the surface of the liquid and the pipe wall. If to consider equation (3) in expression (2) and simplify, we get:

$$\rho\pi R^2(\ell - s)\frac{dv}{ds}v = Pf - 2\pi R(\ell - s)\mu v - \rho g s f \sin\phi \tag{4}$$

Since the speed in the first approximation is small, if to ignore the resistance force, we get the following equation from expression (4):

$$\rho\pi R^2(\ell - s)\frac{dv}{ds}v = Pf - \rho g s f \sin\phi \tag{5}$$

If to integrate the differential equation (5), we get:

$$P = \frac{\rho v^2}{2\ln 2} + \frac{\rho g \ell \sin\phi}{\ln 2}\left(\ln 2 - \frac{1}{2}\right) \tag{6}$$

By expression (6), giving the value of v, it is possible to calculate the pressure needed to squeeze out half of the liquid collected in the pipeline.

In the second option, after the level of the liquid in the pipeline falls to the height H, the pressure required to raise it is found as follows.

The equation of motion of liquid in a pipe:

$$m\frac{dv}{ds}v = P \cdot f - \rho g f(H - s\sin\phi) \tag{7}$$

$$m = \rho f\left(\frac{\ell}{2} - s\right)$$

If to substitute the mass of the liquid in equation (7), we get it:

$$\rho f\left(\frac{\ell}{2}s\right)v\frac{dv}{ds} = Pf - \rho g f(H - s\sin\phi) \tag{8}$$

If to integrate the differential equation (8), we get

$$P = \frac{\rho v^2}{2\ln 2} + \rho g\left(H\ln 2 + \frac{\ell}{4}\sin\phi - \frac{\ell}{2}\ln 2\sin\phi\right)\frac{1}{\ln 2} \tag{9}$$

Considering the equations (6) and (9), the parameters of the pipes, l =3000m; H=200m; R=0.15m; ϱ = 10^3 kg/m^3; Numerical reports were made at values of v= 0.5m/sec. The results of the reports show that the pressure required to remove the first half of the liquid collected in the pipe is P≅0.3ϱgH, and to remove the second half is P ≅ (0.7÷1)ϱgH, that is, for the considered case P_{max} ≅ (1.4÷2.0) MPa, it is possible to completely clean the liquid accumulated in the pipe.

Based on the results of field research, the working pressure required to compress and remove the liquid collected from the pipe passing through the bottom of the sea was determined by means of a mathematical report. In order to ensure unhindered transportation of low-pressure gases between deep water foundations, high pressure (P ≅ 8-10 MPa) supplied to the gas lift system in separate foundations is drawn from the gas lines and low-pressure gas (P=1.5-2.0 MPa) should be given to the line.

Initially, the following technological scheme (Fig. 1) is proposed to ensure unhindered transportation of low-pressure gases between DWFs:

According to the scheme, a gas line (1.5-2.0 MPa) is taken (3) in addition to the high-pressure gas pipelines (1) supplied to the gas lift system (10) from DWF and supplied to the low-pressure gas line (5). Due to the high-pressure gas generated in the system, the liquid phase falling on the pipe is compressed and removed and collected in the liquid tank (8) located on the base.

The proposed method is simple and can be performed by making some changes in the technology of the field equipment located in the foundations. Based on the results of the research and analysis of the low-pressure gas lines to be supplied from the deep-water foundations to the FCS, the following scientific and technical proposals have been developed to ensure the unhindered transportation of gases. The results of the research and mining works carried out in the DWF showed that it is possible to ensure the unhindered transportation of low-pressure and high-pressure gases from deep seabeds to FCS.

The proposed scheme for the transportation of low-pressure gases between DWFs (Fig. 1).

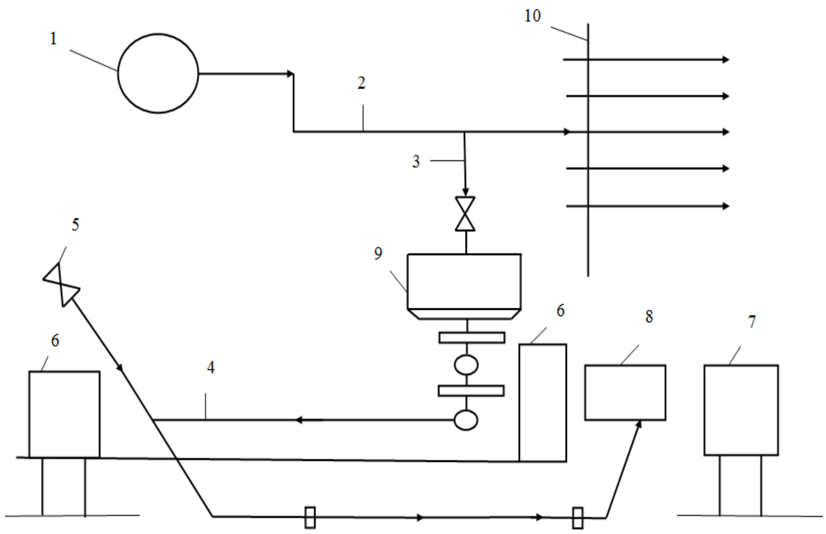

Figure 1: *1-high pressure gas condensate well; 2,3,4- high pressure gas line; 5- low pressure gas line; 6,7- DWFs; 8-liquid tank; 9- capacity for reagent; 10- gas line supplied to gas lift wells*

III. Conclusions

The purpose of reducing the risk of hydrate formation in the system of gathering, preparing for transporting and transportation of natural and associated gases is to find the rate of consumption of the reagent.

Improvement of the internal elements of the separators operated in each base where the waste gases are collected and installation of two and multi-stage separator devices in the technology.

Preparation and reporting of design documents for the construction of the separator and its internal elements.

The use of gel-containing pistons to remove the liquid falling in the low-pressure gas transport system.

Using mechanical pistons to clean the gas lines from the liquid mixture.

Creation of a foaming system based on foaming reagents of different composition and supply to the gas line.

Abstract

Wear and deterioration of the technical condition of the gas distribution mechanism during operation leads to a malfunction of the diesel engine, a decrease in its power, an increase in specific fuel consumption, the formation of carbon deposits on pistons and parts of nozzle sprayers, accelerated wear of the crank mechanism. The need for restoration is dictated by the low post-repair resource of these parts. The currently existing methods for restoring guide bushings are complex and expensive. The chemical method of coating deposition is very promising and simple, since a relatively thin coating layer provides the necessary performance properties to the surfaces of the parts. This article presents one of the ways to restore the guide bushings, with the results of the conducted research.

Keywords: resource, restoration, timing mechanism, guide sleeve, wear, part

I. Introduction

One of the main components of which is the valve group: valve, seat and guide sleeve. The bushing is the main resource-determining link and when it is worn out, the entire gas distribution mechanism cannot work normally. Choosing the optimal way to restore the performance of worn-out machine parts is one of the main issues in the development of technological processes. When applied by chemical deposition on such coatings, there is no thermal effect on the part, leading to its warping, a change in the structure of the base metal and its physico-mechanical properties.

Ni-P-Cu coatings are more promising for restoring the operability of valve guide bushings. When using this method, the cost of expensive equipment is not required, since the equipment of electroplating workshops can be used when applying chemical coatings. In this regard, the urgent task of repair production is to develop a technology for restoring guide bushings using hard and wear-resistant coatings.

II. Results

The formation of the chemical coating was carried out in acidic solutions at a temperature of 90-95 ° C. These modes were chosen as ensuring the formation of high-quality coatings in a stable solution with sufficiently high deformation and strength properties, high adhesion strength and deposition rate. The deformation and strength properties of the coatings were studied according to the standard procedure (GOST 11262). The thickness of the coating on the samples varied from 10 to 300 microns. The samples for wear tests were rollers with a diameter of 50mm and a width of

12mm coated with Ni-P-Cu alloy and pads with a width of 10mm. When studying the deformation and strength properties of Ni-P-Cu chemical coatings, studies were carried out on samples with a copper content from 0 to 1.5% under various heat treatment modes. The microhardness of the coatings was determined on the PMT-3 device by indentation of a diamond pyramid according to GOST 9450-76. For this purpose, cylindrical samples with a diameter of 10mm and a height of 40mm were pre-made.

The coating was applied to a polished, polished, and then degreased surface. The tests were carried out at a load of 50 g. All samples coated with the Ni-P-Cu chemical alloy were subjected to heat treatment. The thermal treatment of the coatings was carried out in a muffle furnace for an hour. To measure the roughness of the surfaces of the semi-finished coatings, a profilograph profilometer mod. 2.01 of the Kalibr plant was used. The structure of the obtained Ni-P-Cu coatings was studied using a MIM-7 microscope.

The elemental composition of the coating and the presence of copper in it were determined using laser emission analysis. The research was carried out on a Carl Zeiss installation. Jena, consisting of an LMA-10 laser microanalyzer with a solid-state laser and a PGS-2 spectrograph.

III. Discussion

The wear resistance of the Ni-P-Cu coating was evaluated on the SMC-2 laboratory installation according to the roller-deck scheme. The pads were made of 40KHN steel. The hardness of the pad was 55...60HRC. Ni-P-Cu coating was applied to the rollers. The tests were carried out in the load range from 6.0 MPa to 12.0 MPa. The tests were carried out on M-10G2 engine oil. Operational comparative tests of engines with restored and serial guide bushings were carried out on MAZ vehicles with YAMZ 236 and YaMZ 238 engines. Before operational tests, experimental engines with restored and serial valve guide bushings were adjusted and run-in on the stand for 10 hours. During the operational tests, the following were monitored: engine operating time and performance indicators [1-15].

One of the main factors affecting the properties of the coating is the temperature of the solution, with a change in which the copper content in the coating changes (Fig. 1), which strongly affects the rate of deposition of the coating.

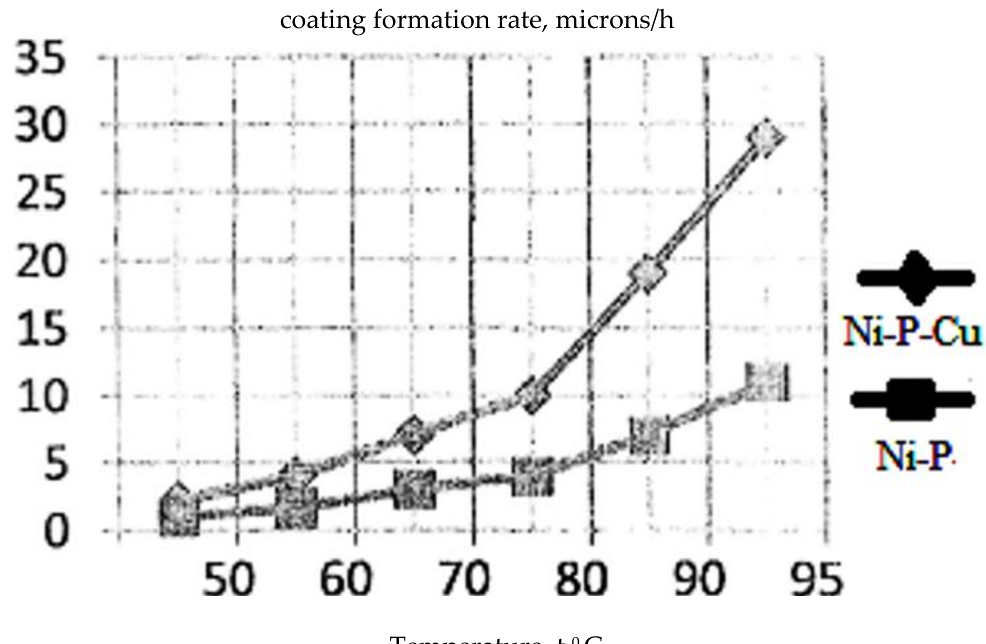

Figure 1: *Dependence of the coating formation rate on the solution temperature*

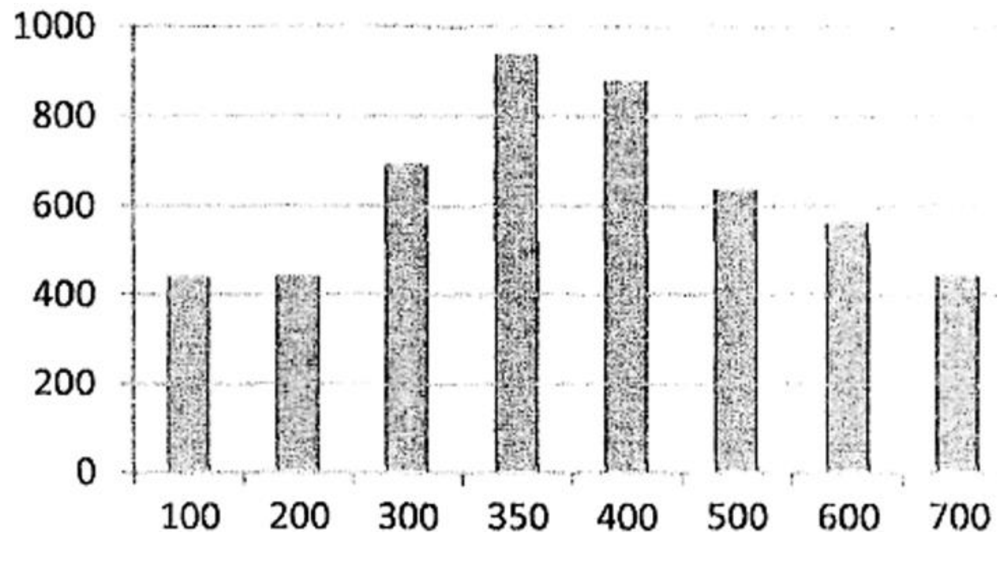
Comparison of Ni-P-Cu coatings before and after heat treatment shows that the presence of heat treatment eliminates layering in the coating and promotes the formation of a more finely crystalline uniform structure. After heating, the layering in the sediments disappears, and the size of the Ni3P particles is further enlarged. When the coatings are heated, phosphorus diffuses from them into the base metal, at the boundary of which a new phase is formed, probably iron phosphide Fe3P.

The precipitates of the chemically reduced coating immediately after their preparation, characterized by an amorphous structure with a random distribution of phosphorus in it, are metastable both in terms of "crystallinity" and in terms of "equilibrium" of the system of a mixture of a solid solution of phosphorus in nickel and a Ni3P compound. When chemically reduced nickel is heated, the amorphous precipitate turns into a crystalline one, which corresponds to two phases, namely the nickel phase (more precisely, the solid solution of phosphorus in nickel) and the intermetallic compound Ni3P. As the heating temperature increases, the amount of Ni3P phase increases due to the decomposition of the solid solution.

The conditions of formation of nickel-phosphorus-copper coatings and their structural features have a decisive influence on their performance characteristics. The heat treatment consists in heating the Ni-P-Cu coated part to a temperature of 400 ° C and keeping it at this temperature for at least 1 hour. The dependence of microhardness on the heat treatment temperature is shown in Figure 2. It should be noted that the disappearance of the amorphous component and the appearance of crystalline nickel and the Ni3P phase occurs after the first minute of annealing, but the maximum hardness is achieved much later. This can be caused by two successive processes: the transformation of a supercooled "liquid" solution into a supersaturated crystalline one and the precipitation of Ni3P from the latter.

In the case of heat treatment at 200 ° C, no changes in hardness occurred even with prolonged heating for 21 hours. As a result, it was found that the maximum microhardness of the Ni-P-Cu coating is 10 Gpa. The average value of the roughness parameter of the Ni-P-Cu chemical coating was 0.08microns.

microhardness, kg/mm^2



Temperature t ^{0}C

Figure 2: *Dependence of the microhardness of the coating on the heat treatment condition*

Comparative laboratory tests have shown that nickel-phosphorus-copper coatings have a wear resistance 1.5 times higher than 40KHN steel. The setting of samples made of 40KHN steel occurs after 0.83 h at a load of 1.25 kN, and samples with a chemical Ni-P-Cu coating after 1.41 h at a load of 2.12 kN. The increase in the setting load of Ni-P-Cu coated samples is explained by the characteristics of this alloy.

In addition, the absence of cracks also prevents the friction surfaces from setting, since the detached particles, falling into the gap of the friction surfaces, can cause them to jam. The high wear resistance of the Ni-P-Cu coating is due to the significant microhardness of such coatings, as well as structural features.

The corrosion tests carried out made it possible to establish that the Ni-P-Cu alloy after heat treatment at 400 °C has a corrosion resistance 1.2 times higher than 40KHN steel.

Since corrosion processes begin on exposed surfaces, a denser and finer grain structure prevents the spread of corrosion into the depth of the coating due to the absence of cracks and pores in it. Based on the conducted laboratory studies, a technology for restoring the guide bushings of the YaMZ-236 and YaMZ-238 engines was developed. According to the data obtained from operational tests, the resource of the guide bushings of YAMZ engine valves, restored using a chemical coating of nickel-phosphorus-copper, is 1.3-1.5 times higher than the resource of serial guide bushings installed by the manufacturer [16-19].

IV. Conclusion

1. When carrying out wear tests on the SMC-2 friction machine, the wear of samples coated with a nickel-phosphorus-copper chemical coating is 1.5 times less than samples made of 40KHN steel. The setting load of samples coated with Ni-P-Cu coating is 1.2 times higher than samples made of 40KHN steel.

2. The corrosion resistance of the studied samples coated with Ni-P-Cu chemical coating exceeds the corrosion resistance of 40KHN steel samples by 1.2 times.

3. The operational tests carried out showed that the service life of the valve guide bushings, restored using a chemical coating of nickel-phosphorus-copper, is 1.3-1.5 times higher than the serial ones.

Abstract

The extreme conditions of firefighting personnel are characterized by strong psychotraumatic factors from a psychological point of view. Psychological preparation for extinguishing fires in difficult conditions and eliminating their consequences requires improving the efficiency of combat operations, saving people from fires, protecting material values from destruction, and raising the level of psychological resilience, which is the basis of the rescuers' own safety.

Keywords: emergency events, psychological preparation, psychological resilience, psychotrauma, mental processes, safety

I. Introduction

On May 19, 2015, the fire that occurred in a multi-storey residential building located at 200/36 Azadlig Avenue, Binagadi District, Baku city, alarmed not only the residents of the building, but almost the entire population. Dozens of people who did not live in that building, relatives and acquaintances, ordinary citizens also went to the scene. Most parents were inevitably worried about their children. It is possible that this sensitivity becomes chronic in some people.

In psychology, this is called psychotrauma, i.e., anxiety disorder. It was possible to clearly feel this shock and anxiety from the statuses shared on social networks about the fire [1].

The reason for this was people's psychological unpreparedness for events. Psychologists have determined that people who are psychologically unprepared for natural events, man-made accidents, military armed struggle, and ecological disasters have a deplorable negative effect on both the events and the results of activities during the elimination of their consequences [2].

In the article, in order to increase the efficiency of solving fire safety problems, the psychological preparation of fire extinguishing personnel - as a system of purposeful effects of the actions of their leaders during emergency situations in peace and military times, gaining experience in successful operation in conditions modeled by QX and DTI, development of important qualities for the profession and personal self-improvement in military personnel, rescuers and the ways and methods of achieving the goal of forming and strengthening psychological stability by conducting psychological training in civil workers were discussed.

The formation of professional continuity (preparation) of employees of the Ministry of Emergency Situations (MES) of the Republic of Azerbaijan during the course of daily service and combat training activities is carried out as part of the main duties. The main purpose of this activity is to change the nature of the impact of the stress that occurs in extreme conditions on the functioning of the psyche and to influence the activity of military personnel (rescuers): it should cover mental states of neutrality and even stimulating states.

II. Methods

During the training and upbringing of each specialist of the Ministry of Emergency Situations, the qualities necessary for the formation of a wide range of professional activities are provided. However, the experience of performing tasks in extreme conditions shows that each previously formed quality, when changing the conditions of the rescuer's activity (natural disaster, accident, catastrophe, the impact of accidents by negative factors, the relief of the area, weather, vision, etc.), in particular, emergency-rescue it may not manifest itself during the transition to the conduct of work. There are also many examples where an expert performs a task successfully for training sessions and does not perform the actions at all well when the conditions are changed. At this time, the passive-defense reflexes actually cause the behavior of the rescuer under the influence of inappropriate conditions and reduce the efficiency of the service activity [3, 4].

So, the novelty factor sometimes plays a decisive role in the emergence of previously formed qualities in a person and in the performance of actions. The task of the head of the psychological training of the personnel is to prepare a preliminary model of possible natural disasters or emergency situations during training and educational exercises. Carrying out the exercises in the conditions corresponding to the real situation makes it easier to form the necessary psychological qualities for professional activity, and the efficiency of the time spent increases. In other words, as a result of daily educational preparation - it means action on the list of unexpected, new, unknown things in emergency situations. Therefore, it provides advance preparation for the measures to completely minimize what is expected and possible to occur in the performance of emergency rescue works.

Let's look at the mechanism of psychological preparation that occurs due to the internal and external influences on the psyche of the conditions created for military personnel (rescuers). In order to get answers to these and other questions, if we approach the essence of the main theoretical and practical issues of psychological training, it is likely that the challenge in the psyche of rescuers is the purposeful formation and strengthening of image models of actions appropriate to the situations. The logic here should be as follows: if in military personnel (rescuers) and the civilian population there is a large amount of mental images corresponding to the upcoming events, which are maximally suitable for the extreme conditions of fire, formed qualities, then there is less possibility of falling into a situation of unpredictability, uncertainty and novelty, and as a rule , in turn creates a passive-defense reflex that leads to the formation of harmony in the work, the commission of unlikely actions is eliminated.

To better understand this issue, let's look at what the action image itself reflects. A mental image is what a person sees, hears and experiences. In the mind of the savior, his actions were like a psychological model and nothing else. This is not a picture of any situation, but it is of greater importance. This process is quite complicated and temporary, it is not a reflection of objective reality, but it also ensures the establishment of the rescuer's future activities, adequate to the real situation for the purpose of re-creating the images experienced and seen before. Operational structure - the motives, needs and goals of military personnel (rescuers) act as regulators of their professional activity. Therefore, it will be methodologically correct if, during the course of all daily activities, the manager will stick to the organization of his psychological preparation and will regularly spend his efforts on the formation of the concepts and the basic model of the upcoming operations.

It is important to take into account that for rescuers, the manner of performing this or that action and its specific content, as well as its importance, are defined. It is a fact that it looks very good in terms of good preparation in relation to the profession, in terms of saving, implementing, managing, etc., skills with high professional qualities. However, in extreme conditions, if the basic concepts of the model of future activity are not well developed, calling their actions purposeful, then it is likely that the tasks will not be performed effectively.

The level of extremity of military servicemen (rescuers), psychological properties of personality, self-regulatory (directive) mechanism and influencing factors of FH conditions is determined by psychological continuity. However, if the mental stability of the rescuer is determined by the individual typological characteristics, emotional irritation and emotional disturbance occur, then first of all, the clear expression of the subject's volitional effort and ability is determined by the degree of his emotionality. In addition, psychological resilience, for example, in extreme conditions, can be acquired or innately determined by the subject's personal qualities and psychophysiological mechanisms, which allow to consciously or unconsciously react (resistance) to emotogenic factors.

III. Results

As a result of the psychological preparation of military personnel (rescuers) during their daily activities, psychological stability (readiness) is formed in time, that is, the system of psychological qualities determines the potential capabilities of rescuers to successfully carry out emergency rescue and other urgent tasks and to overcome difficulties [5].

It is very important to form the conditions that ensure the success of achieving the goals of the level of mobilization and the desire of the psyche to overcome the difficulties of the upcoming service activity, the state of psychological satisfaction of the military personnel (rescuers) immediately before the tasks set in the process of psychological preparation.

The analysis of psychological preparation shows that the main place in its structure is occupied by psychological qualities - psychological satisfaction and persistence. The same components appear in the structure of psychological satisfaction and psychological sustainability: motivational, emotional, cognitive, intellectual, operational and voluntary.

The motivational component comes from the desire of military personnel (rescuers), specialists to overcome obstacles, show themselves to withstand the difficulties of the service, courage, determination, initiative to carry out emergency rescue work, what they are capable of, self-affirmation in the rescue team.

The emotional component is expressed in the confidence of military personnel (rescuers) and employees, as well as in their doubts about their abilities to perform this or that voluminous work, and in the feeling of excitement and satisfaction in the fulfillment of the assigned tasks.

The cognitive component characterizes the degree of understanding and understanding of the tasks, the assessment of the possibilities of managing one's own behavior and psyche, and the perceptions of the nature of the difficulties of the upcoming emergency rescue work.

The intellectual component characterizes the rescuer's thinking type and mental capacity.

The operational or mobile component refers to the methods and tools used by the specialist during emergency rescue operations.

The voluntary component is expressed in the ability to overcome stress and fatigue, subordination of all forces to achieve, determination to fulfill the tasks set and self-control and self-regulation in the process of fulfillment, patience, self-control.

In the emergence of readiness, motivational, cognitive, intellectual components take the leading place, followed by active, voluntary and emotional psychological components.

The will takes a leading position in the formation of psychological stability. Because willpower is related to purposefulness, focus, regularity, consistency, and a systematic way of thinking, it helps overcome whatever might undermine effort.

The lack of willpower can lead to the fact that people set very insignificant life goals for themselves, show laziness in their activities, instead of being in a healthy self-criticism spirit, they engage in unnecessary and useless regrets, feeling guilty. The psychological stability of the employee of the Ministry of Internal Affairs of Azerbaijan in his professional activity is characterized by a great feeling of confidence as a successful result of this activity, related to the motivational characteristics of achieving the goal. However, this promotion is typical only for certain types of people, who always intend to achieve the exact result.

Volitional effort is the energy source of emotions and thoughts, with the help of which we send mental energy from one source to another energy source, to a new address. The will eliminates the conflicts of various directions of psychic energies and sends a psychic energy signal to the physiological level, activates other forms of energy, in particular, changes the way of life, overcomes distance, changes the direction of unpleasant and non-level works, etc.

We do not know faceless cold will in life. For example, I.M. Sechenov saw the cause of human activity in stimulating the sense of hearing that gives a certain meaning to his actions (in physical passions), in his thinking and in the actions of his spiritual feelings.

M.Y. Basov (1922) made the directing function of the will the subject of his analysis. The will is understood as a mental mechanism, its identity as a regulator (director) of mental functions, their combination or change in accordance with the problem to be solved. M.Y.Basov wrote that the personality's power over its spiritual conditions is possible when its spirituality contains only one regulatory factor. This factor is a strong personality and circumstances. The name of this factor is will. According to him, the will-directing function always focuses on the "act of regulation". M.Y. Basov considers voluntary effort as "directive subjective expression of voluntary function" and attention as "the same event, only show different terms". According to him, perception, thinking, emotions (feelings) are regulated by changing the content of consciousness, i.e. by distraction Basov believed that the will does not have the power to create actions, thoughts or abilities, but only regulates them.

The idea of regulating various mental processes and voluntary activity of a person L.S. It was developed in the works of Vygotsky. Accepting the will function of choice and compulsion of action, L.S. Vygotsky considered basic mental processes and voluntary regulation of behavior in the problem of will. And from here, the question of the establishment of the will, the issue of the will in its framework changes from here. The original problem is not a product of action, but "self-handling" shows originality. In this problem, as one of the stages of "mastering one's own behavior" of the will, we call the "mental continuity" of a person as a formative. K. Levin believes that the control of emotions (affects) and actions is the essence of the human will.

Most national and foreign authors in the field of psychology (Collins and others) define will as a special human ability. Even Aristotle noted that the will determines the ability of activity that arises from the person himself. Like D. Locke, he understood the human will as the ability to act. Every real voluntary action, L.S. Vygotsky noted that it is a selective act, which includes conscious choice and decision-making. L.S. Vygotsky's function of the will is to create an activity, noting its motivation and determination, selection and regulation of the goal, implementation of the activity and the participation of personal education with the initiator, he defines various characteristics of his activity, first of all, the qualities of the will (perseverance, determination, perseverance, etc.). For example, bravery and determination in the field of will, overcoming the fear of death, manifests itself in rescuers.

Rescuers develop willpower in the following directions:

- The formation of individual physiological and psychological tolerance to prepare for the elimination of various difficulties in the intense rhythm of the activity in extreme conditions;
- Increasing the level of continuity of professional skills for flexible and timely performance of duties;

- Formation of psychological preparation for unexpected actions;

- By creating and strengthening psychological qualities in rescuers, by developing in them unpretentiousness (lack of satisfaction), simplicity (non-demandingness), moderation in demands and wishes, which can replace the tendency to comfort and eliminate the inability to perform emergency rescue work in the event of unfavorable natural and climatic conditions;

- The formation of group unity with psychological continuity based on the performance of service duties of Azerbaijan Ministry of Defense employees within the rescue team.

Undoubtedly, during the lifeguards' daily service and combat training activities, psychological preparation or pre-sustainability is formed, which, as a system of psychological qualities (knowledge, habits and skills), conditions a person's potential opportunities to successfully overcome difficulties and successfully fulfill the tasks.

In the process of receiving tasks and directly directing human resources to their fulfillment, the psychological preparation for the MFA specialists of the Republic of Azerbaijan to start their fulfillment at any time is included in the first plan. The mobilization and enthusiasm, activity and direction of rescuers' psyche to overcome any difficulty should be taught through special exercises. That is, psychological preparation is a stage of historical transition from everyday life situations to the performance of official duties.

With the beginning of the performance of new tasks (assignments), psychological continuity begins to manifest itself in the form of the experience of new, previously absent qualities in the form of combinations in the organization of activity and the preservation of the functionality of previously formed or with the formation of new qualities. In other words, at the same time, long-term preparation forms psychological stability in advance. These abilities are formed on the basis of previously acquired knowledge, skills, habits, experiences and other important professional qualities.

Timely psychological preparation should not reduce the ability of rescuers to work full-time, that is, increase the efficiency of their activities in the first hours after the disaster, and allow them to help the victims the most at that time. The preparation of specialists for action in the field of Emergency Situations in many cases significantly reduces human and material damage and losses.

In the organization of psychological training, the head of the accident and rescue units should proceed from the principle of pre-formation of the main concepts of the action model in relation to images. This means that any intention in the implementation of psychological preparation should be based on the importance of the tasks and the strengthening of beliefs, the collection of ideas about the conditions for performing emergency rescue work, and the strengthening of motivational goals. For this purpose, self-proven methods of conducting psychological training can be widely applied, mainly methods related to verbal and verbal influence of commanders and chiefs, methods of persuading, inducing, influencing the psychology of subordinates by other specialists [6, 7].

It should be noted that psychological preparation for solving tasks alone, setting goals, is not enough in a combat situation. Successful rescue operations often depend on the formation of realistic mental images. For this, lifeguards must fill the mental image of the professional activity model with what can be perceived by the senses, physically (body) by performing training exercises during day and night training.

It is possible to widely use the methods that allow to strengthen the model of actions on the basis of images of the qualities that are necessary for professionalism. They may include: - exercises and actions in military units, ships, tankdromes, airfields, training grounds, fire drills, special simulators, etc.; - obstacles, fences, debris area, special lanes for eliminating water borders, single obstacle lane, physical and sports activities of rescuers; - sports games and competitions; - psychological actions for purposeful development of intellectual, emotional and voluntary qualities; - the organization of psychological trainings on the strengthening of the collective is of particular importance for the formation of psychological compatibility, collectivism, reciprocity, etc.

Pedagogical-psychological literature has many suggestions about the organization and implementation of psychological training with different approaches, taking into account the organization and implementation of psychological training, conducting psychological training with special measures or conducting training (operational planning department) at the same time during education (educational institutions). Because training, upbringing and psychological preparation are actually closely related and interdependent, it is necessary to look at what qualities, characteristics, mental processes and situations are formed in each of the listed areas. Carrying out the most general analysis, it can be noted that the behavioral customs and habits of the employees of the Ministry of Internal Affairs of the Republic of Azerbaijan are improved in various conditions during the education process, as well as their voluntary qualities are developed: the emotional-voluntary field of personality is developed and its adaptation to new conditions is carried out; they envisage rescuers purposefully carrying out emergency rescue work under conditions of possible difficulties, they are instilled with citizenship, courage, perseverance, perseverance, confidence, etc., the importance of their own activities.

In the training process, moral-will qualities and emotions (courage, bravery, courage, determination, initiative, fulfillment of ready tasks, sense of collectivism) are formed and strengthened, and motivational goals are activated in order to provide the necessary assistance to the victims; through the collection of knowledge about the ideas relevant to these or other emergency situations, the habits and skills corresponding to the development of psychological preparation and resilience take place [7].

However, it would not be correct to refer to training and education to form psychological resilience. The tasks solved by training and upbringing are wider than psychological preparation. However, among these tasks, it serves to form psychological and special qualities that can be solved only in the process of psychological preparation exercises, which are necessary for the performance of a number of tasks. For example, development and strengthening of skills and habits needed to perform specific tasks; Special qualities characteristic for increasing the cognitive processes, motives, and skills of the Azerbaijan Ministry of Internal Affairs specialist, or caution, vision, thinking, coordination in movement, activation of stress tolerance, etc. in lifeguards.

Thus, formation of important professional qualities (courage, heroism, citizenship, etc.) is carried out with the help of psychological preparation exercises. It is more characteristic of them than specific methods (training, ideomotor exercises, studying the main signs of characteristic situations, etc.)[8,9].

Specific training and other professional qualities are developed in rescuers with the aim of understanding the issues of tasks set in the process of psychological preparation, creating confidence in rescuers in the necessity of their unconditional fulfillment.

The main directions of psychological training of military personnel (rescuers) and employees:

- preparation of rescuers for all kinds of self-sacrifice, formation of beliefs, behavioral style of saving victims, formation of scientifically based knowledge on committing selfless actions for the sake of saving victims;
- raising the level of professional skills and habits, psychological and physiological endurance, unpretentiousness in desires and needs, simplicity and gentleness in lifeguards;
- to be involved in state policy, to instill trust in commanders, chiefs and leadership, unconditional fulfillment of orders and development of goals for subordination, loyalty, reliability in education;
- reduction of mental injuries.

Conducting rescue work (adequacy of actions and mental state in the conditions of carrying out accident-rescue work) requires strict adherence to the principles of psychological preparation.

IV. Conclusion

During the performance of the tasks solved in the rescue units of the military formations and in various parts, the psychological preparation depends on the professional-tactical conditioning of the content, the degree of ensuring content activity safety during the execution of training and work depends to a large extent on the efficiency of the work done. In addition, in the situations of created service and combat tasks, compliance with the psychological compatibility of training and service tasks increases the quality of performance of combat tasks.

Psychological stability is a complex of special measures included in the professional training system and the entire rescue service. With the direct help of psychological preparation, providing maximum adaptation between individual and collective professional characteristics, specialty elements and skills, emergency rescue and other urgent tasks, and real psychological requirements is important in eliminating psychotrauma during activity.

ANALYTICAL DETERMINATION OF THE CRITICAL VALUE OF WELL FLOW RATE DURING FLOWING OPERATION

Yusif Orujov, Sakit Abbasov

•

Azerbaijan State Oil and Industry University
yusif144@mail.ru
s.h.abbasov@mail.ru

Abstract

The purpose of this study is to propose a methodology for determining the critical flow rate in flowing wells to prevent the collapse of the productive formation, taking into account the homogeneity of the rocks. The method of operating wells, in which the rise of hydrocarbons from the bottom of the well to the surface occurs due to natural (reservoir) energy, is called flowing. Flowing of oil wells occurs due to hydrostatic pressure or the energy of compressed gas, as well as due to the energy of compressed rocks. The influx of oil to the bottom of wells occurs due to the difference between reservoir and bottomhole pressure. In the case when the pressure of the liquid column (to the wellhead of the filled well) is less than the reservoir pressure, the well will flow. Flowing well production is a method of hydrocarbon production in which the pressure in the formation is high enough to cause the product (such as oil or natural gas) to spontaneously rise to the surface without the additional use of artificial pumps or other devices. Basic concepts of flowing include:

1. Hydrostatic head: The natural pressure created by the hydrostatic column of fluid in a formation allows production to rise to the surface.

2. Compressed Gas Energy: In some cases, the presence of compressed natural gas in the formation can provide additional energy to lift production.

3. Energy of compressed rocks: During fracturing or other geological processes, additional dynamic conditions may be created that promote flow.

The influx of oil or gas to the bottom of wells occurs due to the pressure difference between the formation and the bottom. When reservoir pressure exceeds pressure at the bottom, this can lead to flowing - raising production to the surface. Maintaining flowing conditions can be an important aspect of well operation, and engineering efforts may include pressure control, calculations of optimal production rates, use of water injection techniques (If there is water in the formation), and other techniques to ensure efficient production.

Most often, in the flow of wells the gas contained together with oil in the formation plays the main role, including in cases where the gas under reservoir conditions is completely dissolved in oil and a homogeneous liquid moves through the formation. The structure of productive formations can be different, including layered and heterogeneous formations. This can lead to uneven hydrocarbon production and problems with water cut in permeable layers. For successful oil or gas production from such reservoir formations, the difference between the reservoir pressure and the pressure at the bottom of the well plays a key role. If the pressure in the liquid column is lower than the reservoir pressure, the well may begin to flow. Often the gas contained together with oil in the formation plays an important role in the flow of wells. Even if gas is completely dissolved in oil and a homogeneous liquid moves through the reservoir, its presence can significantly affect the pressure and dynamics of production. For example, when the pressure at the bottom decreases, gas can be released from the solution, increasing the volume and pressure inside the well and promoting its flow. Effective management of the production process includes not only pressure control, but also evaluation of gas factors, optimization of production rates and use of water injection technologies to minimize the negative effects of heterogeneity of formations and ensure the most efficient production of hydrocarbons. Flowing of an oil well can occur depending on the operating mode of the energy source, *including hydrostatic pressure or expansion energy of the gas contained in the oil. In some cases, gushing can occur simultaneously due to both energies. Hydrostatic pressure created by the column of oil and other fluids in the formation can be the main source of energy for a blowout. If the formation pressure is high enough and has good permeability, oil can rise to the surface under the influence of this pressure. If the oil contains dissolved gas, its release and expansion when reaching the surface can also contribute to blowout. Gas expansion creates additional pressure inside the well, which can increase the flow of oil and gas to the surface. When both of these mechanisms operate simultaneously, this can lead to more intense flowing and increased hydrocarbon production. However, control over this process is important to avoid unwanted consequences such as oil spills or loss of hydrocarbons into the environment. In this context, engineers and well operators actively monitor and adjust production parameters to ensure safe and efficient operation.*

Keywords: oil and gas condensate field, bottomhole pressure, operating methods, hydrostatic head, acceleration of gravity, fluid filtration, back pressure at the wellhead, stress state, hydrostatic head

I. Introduction

However, most often the main role in the flow of oil wells is played by natural gas contained together with oil in the reservoir. This applies even to situations where gas is completely dissolved in oil and movement through the formation occurs as a homogeneous liquid.

In this case, all the gas is in a dissolved state in the oil, and the bottomhole pressure is determined as the pressure of a column of homogeneous liquid filling the well, according to the formula

$$P_{b.h.} = H\rho g + P_{fr} + P_w \quad (1)$$

where, $P_{b.h.}$ pressure, MPa; H – well depth, m; ϱ – liquid density, kg/m^3; g-free fall acceleration, m/s^2; P_{fr} – hydraulic pressure loss due to friction during fluid movement in pipes, MPa; P_w – back pressure at the wellhead, MPa. Friction pressure losses are determined using the Darcy-Weisbach formula:

$$P_{fr} = \frac{\lambda \cdot L}{d} \cdot \frac{v^2}{2} \cdot \rho \quad (2)$$

where λ is the coefficient of hydraulic resistance; d – diameter of pump-compressor (lifting) pipes, m; ν – speed of fluid movement in the rising pipes, m/s; L – length of the lifting pipes, m. The numerical value of λ is determined depending on the surface roughness of the lifting pipes and the Reynolds criterion:

$$\lambda = \frac{64}{\mathrm{Re}} \quad when\ \mathrm{Re} = \nu \cdot d/\upsilon < 2320 \quad (3)$$

$$\lambda = \frac{0{,}3164}{\sqrt[4]{\mathrm{Re}}} \text{ when } \mathrm{Re} > 2320 \quad (4)$$

where υ is the kinematic viscosity of the liquid, m^2/s.

Bottomhole pressure is determined from the basic equation of fluid inflow to the bottom of the well:

$$P_{b.h.} = P_c - \sqrt[n]{Q/C} \quad (5)$$

where Q is the well flow rate m^3/day;

C – productivity coefficient, this is the ratio of well flow to depression: m^3/(day MPa);

P_c – contour or reservoir pressure, MPa;

n – coefficient equal to 1, when a straight indicator line leaves the origin; if the movement of fluid in the formation obeys Darcy's law, then the speed of fluid movement in the formation is directly proportional to the pressure drop;

n<1, when the line is convex relative to the pressure drop axis;

n>1, when the line is concave relative to the pressure drop axis

Substituting values (2) and (5) into equation (1), the pressure at the wellhead is determined taking into account n=1:

$$P_w = P_{for.} - Q/C - H \cdot g \cdot \rho - \lambda \cdot L/d \cdot \nu^2/2 \cdot \rho \tag{6}$$

In this case, the bottomhole pressure will be determined as follows;

$$P_{b.h.} = P_c - \frac{Q}{C} \tag{7}$$

II. Statement and solution of the problem

It is known that when the operating mode of oil and gas wells is chosen incorrectly, formation collapse occurs, i.e. a critical stress state arises in the formation. Therefore, solving this problem is very important for preventing emergency situations [1÷5].

Let us consider the stressed state of the bottomhole part of the well, taking into account fluid filtration in the formation. Rocks are accepted as an isotropic body. The stress state of the near-wellbore is characterized by the following equilibrium equation (Lame parameters):

$$\frac{d\sigma_r}{dr} + \frac{1}{r}\left(\sigma_r - \sigma_\varphi\right) = 0 \tag{8}$$

r de σ_r, σ_φ - radial and circumferential stress, respectively

It is known that the production rate of wells, i.e. the influx of fluid to the bottom of wells occurs due to the difference between the reservoir and bottomhole pressure. The internal (bottomhole) pressure of the well will take the value as (5).

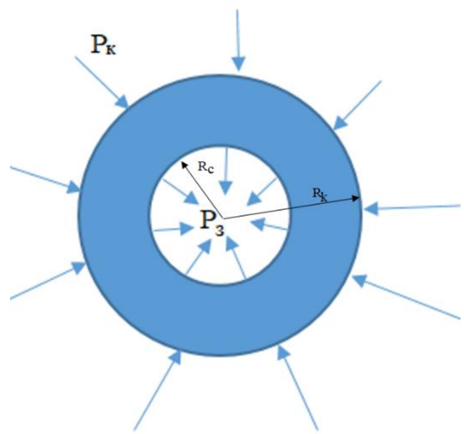

Figure 1: *Stress state at the bottom of the well*

In the case under consideration, the boundary conditions have the form;
at r=R_c; σ_r=$P_{b.h.}$; at r=R_c; σ_r=-P_c. Then the general solution to equation (8) will take the form:

$$\begin{cases} \sigma_r = \dfrac{-R_w^2 P_3 - R_c^2 P_c}{R_c^2 - R_w^2} + \dfrac{R_c^2 R_w^2 (P_{b.h.} + P_c)}{R_c^2 - R_w^2} \cdot \dfrac{1}{r^2} \\ \sigma_\varphi = \dfrac{-R_w^2 P_3 - R_c^2 P_c}{R_c^2 - R_w^2} - \dfrac{R_c^2 R_w^2 (P_{b.h.} + P_c)}{R_c^2 - R_w^2} \cdot \dfrac{1}{r^2} \end{cases} \tag{9}$$

R_w is the radius of the well, R_c is the radius of the formation contour.

Considering that the maximum stress occurs in the inner wall of the well, i.e.

$$\text{at } r = R_c \qquad \sigma_r = P_{b.h.}; \qquad \sigma_\varphi = -P_{b.h.} - \frac{2R_c^2}{R_c^2 - R_w^2} P_c \tag{10}$$

The failure condition for isotropic rocks has the form;

$$\sigma_r^2 + \sigma_\varphi^2 = 2\sigma_t^2 \tag{11}$$

where σ_t is the rock strength limit.

If (10) is taken into account in (11), we obtain the following expression;

$$P_{b.h.}^2 + m^2 P_c P_{b.h.} + 0{,}5 m^4 P_c^2 - \sigma_t^2 = 0 \tag{12}$$

where- $m^2 = \frac{2R_c^2}{R_c^2 - R_w^2}$

Considering that the radius of the formation contour R_c compared to the well radius R_w is too large, therefore $m^2 = \frac{2R_c^2}{R_c^2 - R_w^2}$ will take the value $m^2 \approx 2$

The solution of equation (12) with respect to $P_{b.h.}$ determines the critical value of the bottomhole pressure

$$P_{b.h.} = -P_c \pm \sqrt{\sigma_t^2 - P_c^2} \tag{13}$$

For real solutions, equation (12) must satisfy the following condition:

$$\sigma_t^2 - P_c^2 \geq 0 \tag{14}$$

Conditions (14) are satisfied for any rock.

From (13) we determine the critical value of bottomhole pressure;

$$P_{cr} = \left| -P_c + \sqrt{\sigma_t^2 - P_c^2} \right|$$

If we assume that the movement of fluid in the formation obeys Darcy's law, then the speed of fluid movement in the formation is directly proportional to the pressure drop, i.e. n=1, then for the critical value of the well flow rate Q_{cr}, taking into account the homogeneity of the rocks, we obtain the following expression;

$$Q_{cr} = P_c K \left(2 - \sqrt{\left(\frac{\sigma_t}{P_c}\right)^2 - 1} \right)$$

III. Conclusions

1) A method for calculating the stress state at the wellbore is proposed and the critical value of the bottomhole pressure is determined.

2) Based on this method, the critical value of the well flow rate was determined at which a formation collapse may occur.

Abstract

The paper analyzes the existing methods of calculating the intensity of thermal radiation at fire, which are presented in normative and methodological documents.
It is established that the existing method of calculation contains errors and does not allow obtaining a reliable result. The method of calculation of the conditional probability of people being affected by fire is not suitable for practical application, as outside the burning spill of flammable liquid the UWPL is always equal to zero, and inside the spill the method has no solution.

Keywords: Fire, probability, thermal radiation, oil spill, premises, personnel.

I. Introduction

As it is known, in order to calculate the intensity of thermal radiation at fire there are several normative documents containing the calculation methodology [1÷5]. Sources [1, 2, 3] contain practically the same calculation methodology. All sources give the same formula, but it has different spelling.

The main disadvantage of the considered methodology is that it does not allow to determine the value of the probit function, and hence the value of the conditional probability of defeat of a person located in the focus of combustion. Outside the combustion center at any scale of release (up to 50000m3 of oil was investigated) the probability of human injury is equal to zero. The question arises, who needed to develop such a complex calculation methodology, if the result is known without its implementation: in the area of the spill we have full uncertainty, and beyond its boundaries - zero result. The zero result outside the spill boundary can be declared without performing the calculation.

Some design organizations take the liberty of claiming that in the burned area the conditional probability of human casualties is 100%. This is not true. This assumption has a practical refutation.

Different representation of equations of one and the same methodology in four existing normative documents leads the designer to the state of complete distrust to normative documents. The designer cannot establish the validity of this or that edition of the calculation methodology, because the authors of normative and methodological documents do not respond to the requests of design institutes, referring to the fact that any normative work in the Russian Federation has been stopped with the release of the Federal Law of December 27, 2002 № 184-F3 "On Technical Regulation". The designer is forced to look for additional sources allowing to solve the problem with a higher degree of confidence.

A different methodology is available in the normative document «VNII GOCHS» "Methodology for assessing the consequences of accidents at fire-explosive facilities" (1994) [4]. The use of this methodology allowed to exclude doubtful points in calculations, and also to get the main transition of conditional probability of human casualty with the change of distance to the place of combustible liquid ignition. Comparing the last calculation methodology with the methodology of GOST and NPB, different estimation of heat flux on the surface of burning spills draws attention. If in GOST and NPB for an oil spill fire the intensity of thermal radiation from the flare surface is 10-25 kW/m², and with increasing spill diameter this value decreases and does not exceed 10 kW/m², then in the methodology of VNII GOCHS this value has a constant value of 80 kW/m².

Figure 1 shows the results of calculating the intensity of thermal radiation (ITR) at a distance of 2 m from the boundary of 10 m³ of oil according to the methods of NPB [2], VNII GOCHS [4] in comparison with the experimental data of Taubkin S.I. [5].

Comparison of the presented results reveals the following:

1. The NPB methodology gives a variable value of ITR. At small spill area the intensity increases up to 9 kW/m², after which it stabilizes at a constant level. The level of thermal radiation at any value of the spill area does not pose a danger to humans, as they have time to leave the danger zone before the start of the impact. The conditional probability of injury to a person outside the burning area at any oil spill area is zero.
2. The GOCHS methodology defines ITR as a constant value at a much higher level than the FSS methodology. This methodology ensures smooth transition of the conditional probability of human injury when increasing the distance to the boundary of the spill from one to zero, which corresponds to the physical model of the phenomenon under study, although the constancy of the intensity of thermal radiation itself does not agree with the results of experiments presented in the work of Taubkin S.I.
3. The results of the experiment of Taubkin S.I. indicate that the intensity of thermal radiation should increase with increasing the area of the oil spill. To ensure this condition, it is necessary to change the dependence of the surface radiation of the combustion torch. With the growth of the oil spill area this indicator should increase. In GOST R 12.3047-98 and PNB 105-03 it decreases with increasing spill diameter.

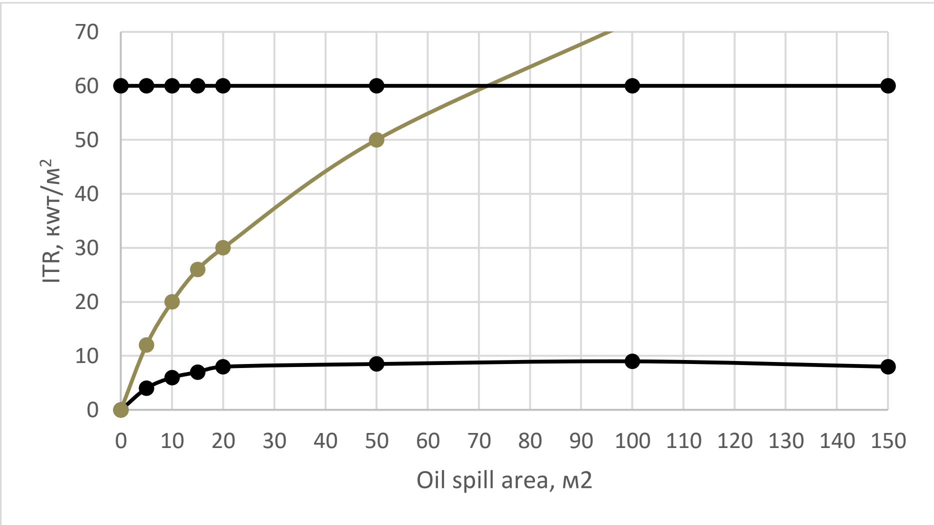

Figure 1: *Comparison of thermal radiation intensity by different methods*

In Fig. 2 shows the dependence of the conditional probability of injury to people from distance to the place of oil release according to the fire safety standards (FSS 105) method. In Fig.3 presents the calculation results in the form of a graph of the dependence of the conditional probability of injury to a person on the distance to the place of the oil release using the authority for civil defense and emergency situations method.

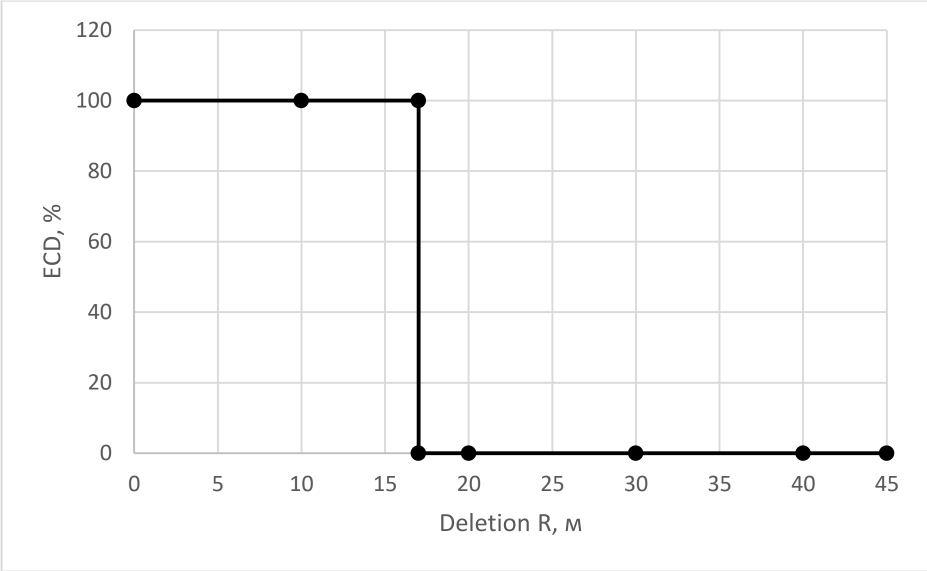

Figure 2: *Dependence of the ECD on the distance to the release site in an oil fire*

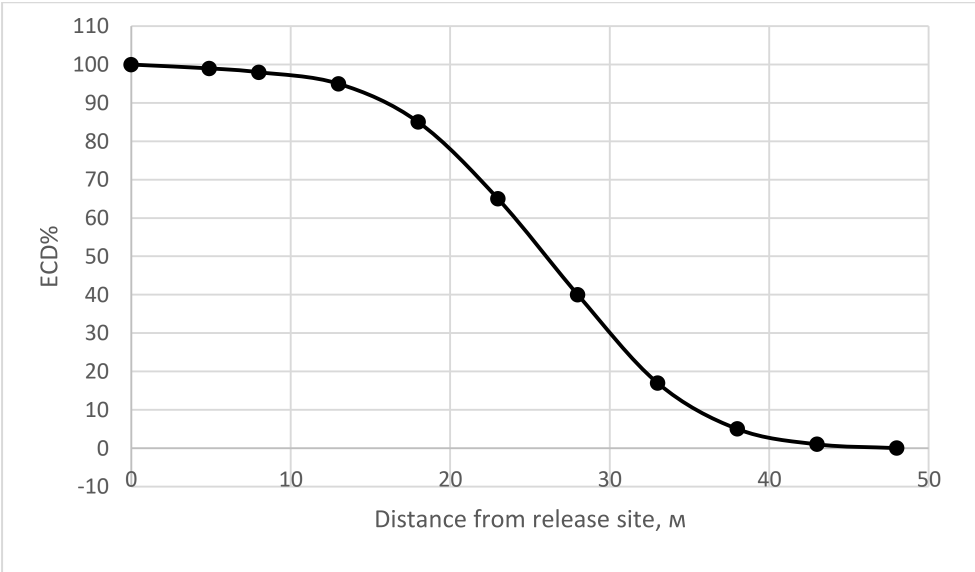

Figure 3: *Conditional probability of people being affected by fire*

A comparison of the considered methods based on the result of calculating the probability of injury to people in a fire revealed, in our opinion, the unsuitability of the fire safety standards method, since it determines the probability of injury depending on the value of the probit function, which is essentially continuous, and the calculation result does not correspond to the continuity condition.

II. Methods

In FSS 105-03 presents methods for calculating the explosion pressure of a hot water supply cloud in an outdoor installation and calculating the conditional probability of injury to a person. Let's consider how these methods are ensured to correspond to each other.

On page 2 of the FSS it is stated that "These standards do not apply to assessing the level of explosion hazard," although all parameters characterizing the fire hazard of outdoor installations are determined by the standards through explosion parameters. In particular, the explosion pressure at an outdoor installation is determined by the equation:

$$\Delta P = P_0(0.8M_{pr}{}^{0.33}\text{Mпр}0.33/r + 3M_{pr}{}^{0.66}/r^2 + 5Mpr/r^3) \qquad (1)$$

Here Mpr – reduced mass of flammable gas participating in the explosion, expressed in TNT equivalent, кg; r – distance to gas release, m.

Analysis of the presented equation reveals that the pressure tends to infinity as r tends to zero. This pressure dependence during the explosion of a hot water cloud is in conflict with the thermodynamics of the process under consideration. It is known that during the explosion of a hot water supply consisting of air and associated petroleum gas components, the pressure cannot exceed 900 kPa. This feature of the hot water supply explosion is indicated in FSS 105-03 on page 7. For example, find the pressure of the explosive at a distance of 0.5 m, as well as the distance from the explosion site of 1 kg of the reduced mass of methane, at which a pressure of 100 kPa and a pressure of 5 kPa are provided. The explosive pressure at a distance of 0.5 m from the release site is 5408 kPa, which significantly exceeds the maximum value of the explosion pressure.

An explosive pressure of 100 kPa is provided at a distance of 2.65 m, and a pressure of 5 kPa is provided at a distance of 20 m from the place of gas release. Using the equation i=123 Mpr 0.66/r, where i is the pressure wave impulse in Pa min, we determine its value at the found values of r.

İ(100)=1230x10.66/2.65=46.42 Pa min; and İ(5)=123x10.66/20=6.15 Pa min.

Based on the values of ΔP and i, determine the value of the probit function-Pr;

Pr=5-0.26Ln(V), where V=(17500/ΔP)8.4 + (290/i)9.3.

Here ΔP – is the excess explosion pressure in Pa.

After substituting the values into the presented equations, we obtain for ΔP equal to 100 kPa and ΔP equal to 5 kPa the values of Rg, respectively, 0.55 and minus 4.25, which corresponds to the conditional probability of human injury equal to zero.

What is the danger of the investigated air pressure levels? The NPB does not contain data on the assessment of the consequences of the explosion. In GOST R 12.3.047-98 [1] we find that an overpressure of 100 kPa leads to the complete destruction of building structures. In case of complete destruction of building structures, people in the building will probably die. Why is there no data about it in the normative document? It should be assumed that the conditional probability of human injury at such a pressure is estimated at 100%. The result of the calculation according to the methodology of the National Fire Safety Regulations gives a different result - 0%

III. Results

1. The existing method of calculating the intensity of thermal radiation in a fire, presented in normative and methodological documents because of the error does not allow to obtain a reliable result.
2. Methods for calculating the conditional probability of people being affected by fire are not suitable for practical application.

Abstract

The article discusses the classification of existing models for predicting given events according to the statistics of all their forecasts and an algorithm for using the intersection or combination of sets of forecasts projections with other models to find the best pairs. The following terms were introduced: "necessary", "sufficient", "unnecessary" and "insufficient" forecasting models. This is discussed…this is discussed in the earthquake forecasting examples, and insufficient similarly be used to predict other events.
We explained what "necessary" and "sufficient" models are. For "unnecessary" models, an algorithm is given for how to choose a hybrid model - the intersection of two or more models that together give a forecast with a higher probability. We also discussed "sufficient" models and an algorithm for selecting such "sufficient" models, the combination of which completely covers all past events, that is, the combination of such "sufficient" models becomes "necessary".
Discusses how one can obtain a "sufficient" or "nearly sufficient" forecasting model by combining "necessary" models, and by combining "sufficient" models to obtain a "necessary" or "almost necessary" models. Also unnecessary models is discussed. In our earlier work, these models were not taken into account; such models were removed from the model database. Similarly, when considering "sufficient" models, if the forecast of the occurrence of an event is specified redundantly, such a model can be excluded from the set of "sufficient" models.
From "sufficient" models we obtain the "necessary" model, which will be both "sufficient" and "necessary" at the same time. In addition, we combine enough models to get the "necessary" model.
All of this uses forecast statistics to strategically select a hybrid model.

Keywords: classification of forecasting models, intersection and combination of forecasting models, necessary, sufficient, unnecessary, and insufficient forecasting models

I. Introduction

When modeling any processes, when it is necessary to test hypotheses about asynchronous processes, forecasting models are often used, which makes it possible to analyze their effectiveness [1,2]. We aim to create a new hybrid model based on existing models that will improve forecast accuracy. This increases the relevance of the topic under discussion.

The most popular existing forecasting model is Bayesian, mainly used to prove asynchronous hypotheses [3,4]. We aim to compare all existing forecasting models with the model we presented and thus obtain a new model (building a forecasting model with parallel data) that further improves forecasting accuracy.

In general, the prediction of asynchronous processes is often not justified because these models are mostly "necessary" and “unsufficient”. “Sufficient” models for predicting defined asynchronous processes either do not exist or are very rare.

Forecasting models can be divided into two groups: “necessary“ models and “sufficient“ models [5,6]. “Necessary” forecasting models are those models whose set of forecasts always includes, those from events that have already occurred. Such models often make incorrect predictions, but they predict every event that occurs. “Sufficient” forecasting models are those whose forecasts are always correct, but they cannot predict all events that occur.

If enough models predict that an event will occur, then that event will happen, but there may be events that they do not predict. In practice, there may be too few such “sufficient” models (for example, in earthquake forecasting) or too many (for example, in economics).

Forecasting models are characterized by a probability of success, which is not unique to statistical models [7,8]. The probability of validity of a forecasting model is the ratio of the number of events With the number of forecasts predicted by a given model, expressed as a percentage, that is, the relative frequency of occurrence (occurrence of an event), expressed in %.

The question arises of when to select the best model from among the “necessary” models, as well as when to identify “sufficient” models. The algorithm in [9] will initially analyze all existing models and identify a pair of models, a triple, a quadruple, etc. models to obtain the appropriate number of “necessary” models, the joint use of which (the intersection of models) gives the best result. Also, from “sufficient” models, a union of “sufficient” models is obtained, which is closer to predicting all occurring events.

Obviously, after each event, a situation may arise when we already have new “necessary” models, or from the old “necessary” models it turns out that some of them are no longer “needed”, that is, they are not predictable. all events I which have already occurred, the models are then reviewed again, removing this unnecessary model from their set and starting to search for new pairs.

As for sufficient models, after each event, new “sufficient” models may appear, whose predictions give better results when combined with the predictions of other models.

Let us consider algorithms for constructing hybrid models using the example of earthquake forecasting. As characteristics of each earthquake, we took the earthquake magnitude, date of occurrence, time, and name of the epicenter.

II. Developing necessary forecasting models

Note: $\mathrm{Mod}_1, \mathrm{Mod}_2, \ldots$ and so on earthquake forecasting models, which provide some predictions based on their predecessors (such as when an earthquake will occur, in what location, and with what magnitude). From these models, only the “necessary” models should be selected; this condition in the case of the earthquake problem means the following: if, for example, during T time an earthquake occurred, n only those models that predicted all these earthquakes should be considered. Let's assume the following models: $ModN_1, ModN_2, \ldots, ModN_n$ (n=5 in the following example), what each model is and what earthquake precursors it predicts are not important when considering the algorithm.

For each model, it is necessary to count the number of forecasts, and the number of justified and unjustified forecasts, and calculate the probability of justification for each model. It is clear that the sum of justified and unjustified forecasts gives the total number of forecasts. As for the probability of justification, it is calculated for each model and determines how many times an earthquake was predicted and how many times an actual earthquake occurred (see Table 1).

Table 1: *Calculation of justification probabilities for one "necessary" model*

Model	Number of forecasts	A successful number of predictions (m)	Unsuccessful number of predictions	Probability of success (%)(P)
$ModN_1$	92	2	90	2.17
$ModN_2$	80	2	78	2.50
$ModN_3$	81	2	79	2.46
$ModN_4$	97	2	95	2.06
$ModN_5$	82	2	80	2.43

In Table 1, m the number of events that occurred, and P_i indicates A_i the number of times all events predicted by the model will occur. From this table, we calculated probabilities of forecasting success for 5 models (%) .

When predicting earthquakes, the author of each model claims that his model is the best, and explains this by the fact that his model predicted all the earthquakes that occurred. Neither of them gives the number of incorrect predictions and therefore does not calculate the probability of their being correct, which are quite small numbers.

The probability of a model's prediction being justified may be quite small but for this model, there is another model that, together with the probability of success, gives us a better result. Let us show the correctness of this with our example.

At the next stage of the algorithm, we need to consider pairs of models. For each model, it is necessary to count the number of realized forecasts, and the number of justified and unjustified forecasts, and also calculate the probability of justification for each pair. Let us introduce the following notation: – $P_{i,j}$is the probability of the forecast cross-section being justified $ModN_i$ and $ModN_j$.

The following table shows these values (see Table 2).

Table 2: *Probabilities of justifying forecast intersections*

$P_i \cap P_j$	P_1	P_2	P_3	P_4	P_5
P_1		9	10	22	27
P_2	9		5	74	40
P_3	10	5		65	37
P_4	22	74	65		63
P_5	25	40	37	63	

If you specify the probability $P_{i,j}$ joint justification two models $ModN_i$ and $ModN_j$, then we obtain the following values (see Table 3):

Table 3: *Probabilities of validity of model predictions for couples*

$P_{1,2}$	$P_{1,3}$	$P_{1,4}$	$P_{1,5}$	$P_{2,3}$	$P_{2,4}$	$P_{2,5}$	$P_{3,4}$	$P_{3,5}$	$P_{4,5}$
9	10	15	25	5	74	40	65	37	63

Let us analyze the constructed table using the corresponding diagram (see **Figure 1**), from which it can be seen that the best result $P_{2,4}$ gives a combination of two models $ModN_2$ and $ModN_4$. The likelihood of their joint acquittal has already increased to 74%. Although individually these models have much lower acquittal rates of 2.50% and 2.06% than the others. In the example discussed, two or more pairs of models may show the same result. At this point, the expert must decide which one should be used.

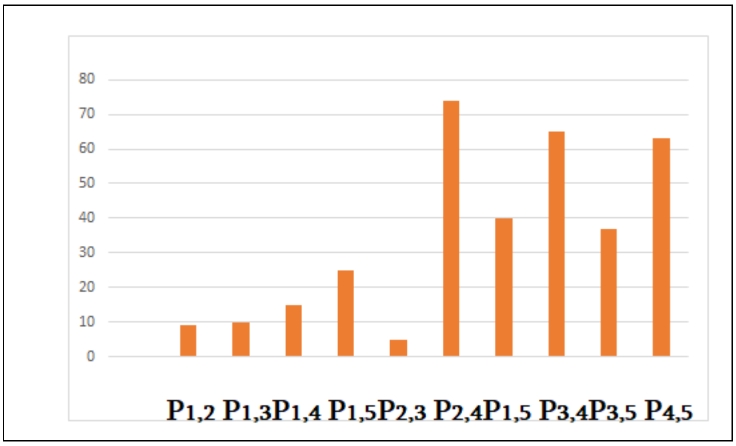

Figure 1: *Probability diagram for justifying pairs of models*

Let us analyze the constructed table using the corresponding diagram (see Figure 1), from which it can be seen that the best result $P_{2,4}$ gives a intersection of of two models $ModN_2$ and $ModN_4$. The likelihood of their joint acquittal has already increased to 74%. Although individually these models have much lower acquittal rates of 2.50% and 2.06% than the others. In the example discussed, two or more pairs of models may show the same result. At this point, the expert must decide which one should be used.

In addition to the "necessary" models, the example of earthquake prediction also included "sufficient" models, for example, there were three models: $ModS_1$, $ModS_2$ and $ModS_3$(see **Table 4**):

Table 4: *Calculation of success probabilities for individual "sufficient" models*

Model	Number of forecasts	A successful number of predictions	Unsuccessful number of predictions	Probability of success (%)
$ModS_1$	7	10	7	100
$ModS_2$	5	10	5	100
$ModS_3$	4	10	4	100

Each "sufficient" model predicted the occurrence of an event, but could not fully predict the occurrence of all events. $ModS_1$ The model predicted the occurrence of the event only in 7 cases out of 10, the second model $ModS_2$ _ðა in 5 cases and the third model $ModS_3$ – ðაin 4 cases. Even if we combine the predictions of these three "sufficient" models, their sum will be 7+5+4>10, but this does not mean that the combination of these models predicted all ten events.

Probabilities need to be calculated successfully for each pair of "sufficient" models, as in the case of "necessary" models (see **Table 5**):

Table 5: *Probabilities success of a combination of forecasts*

$P_i \cup P_j$	*P1*	*P2*	*P3*
P1		8	9
P2	8		10
P3	9	10	

This applies not only to the prediction of earthquakes but also to the prediction of any other event, both static (most often this is the task of forecasting natural disasters) and dynamic prediction, for example, economic fields [1].

It should be said that existing forecasting systems do not divide models into "necessary" models and "sufficient" models. They work with all models, which, if it does not complicate the task, then distorts the accuracy of the forecast.

III. Processing "unnecessary" forecasting models

We discussed a new approach to the forecasting process and demonstrated that forecasting is improved by using "necessary" models of forecast pairs, triplets, quadruples, etc., with a joint review [10,11]. Algorithms have also been formulated on how to determine the "necessary" models, and how to obtain from "necessary" models to „almost sufficient" models. Even for "sufficient" models it is determined how to obtain an „almost necessary" model from them.

Theoretically, it seems that one of the pairs of models may be a "unnecessary model", and the other also a "unnecessary" model, but it is also possible to find a pair (three) that will be close to the "sufficient" model. Let's consider algorithms for processing "unnecessary model " forecasts.

Let's say we are considering a case where an event (for example, an earthquake) occurred several times (for example, 5) and there are three models for predicting this event: *Model I* (I), *Model II* (II).) and *Model III* (III). It is necessary that the model predicts The model must predict at least one…at least one of the events and the set of forecasts has an intersection with the set of forecasts of other forecasting models. *Model I* predicted 3 events, *Model II* predicted 4 events, and *Model III* predicted 1 event (see **Figure 2**). The circles in the figure indicate the events that occurred, and the numbers indicate the names of the models that predicted the occurrence of this event:

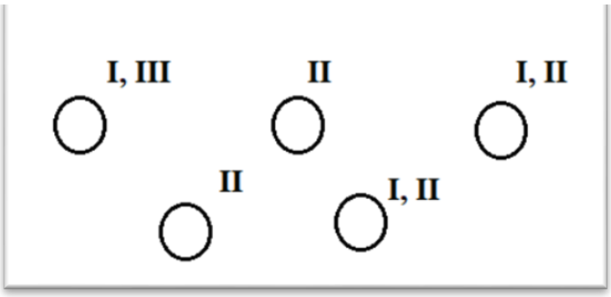

Figure 2: *Forecasting events by forecasting events*

Let us consider the set of events predicted and not predicted by each model, in the case of three models (see Figure 3). Events that these models could not predict are indicated by dots, events that were predicted by these models are indicated by circles.

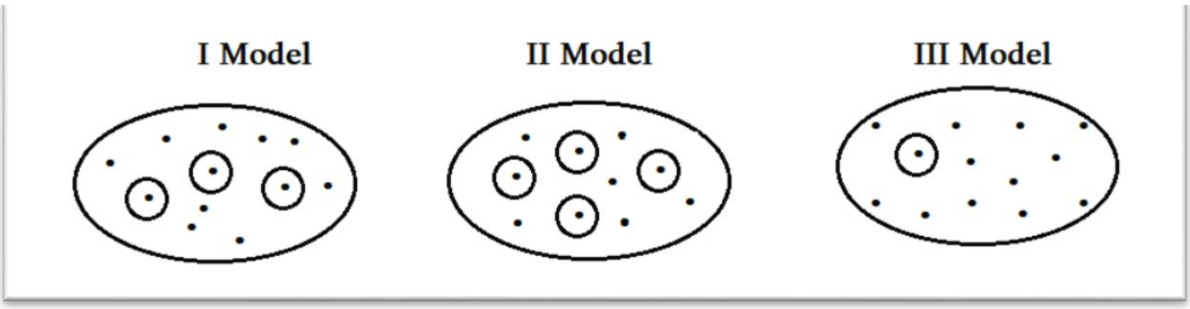

Figure 3: *"Unnecessary" models.*

Let us denote P_i by P_j and N not obligatory models forecasts and consider their intersection P_{ij} (see Figure 4):

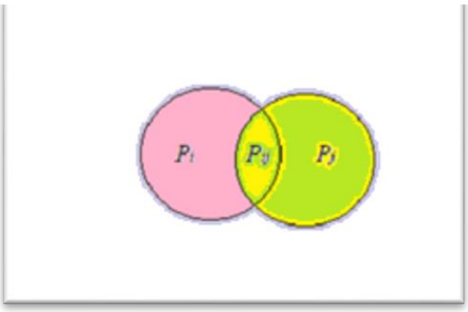

Figure 4: *Intersection of predictions of two models*

If we consider the model's predictions as a possible intersection of sets of events, then three cases can arise here (see Figure 5): when the intersection is greater than the events that have already occurred, when the intersection is smaller, and when they coincide. The event set in the image is marked in blue, and the events in the intersection set are marked in yellow.

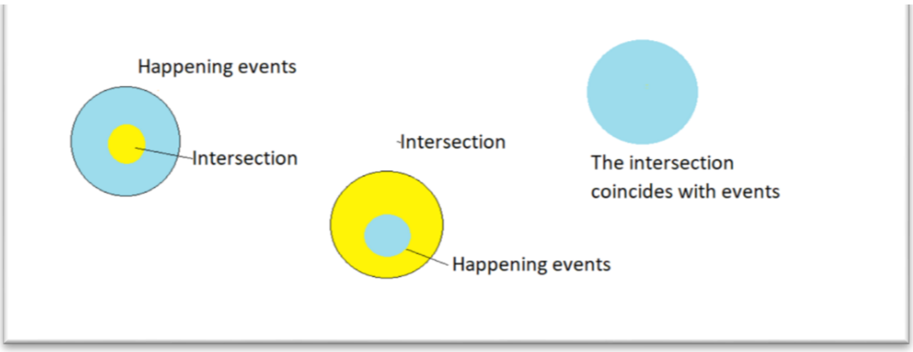

Figure 5: *Occurring events and forecasts of unnecessary models*

If the intersection of models coincides with the set of already existing events, this is the best case, since the set of models involved in the intersection becomes a "sufficient" model for prediction.

Let's look at an example. For each model, count the number of forecasts made, the number of events, and the number of justified and unjustified forecasts, and calculate the probability of justification for each model (see Table 6).

Table 6: *Calculation of justification probabilities for individual "unnecessary" models*

Model	Number of forecasts	A successful number of predictions (m)	Number of events that occurred	Unsuccessful number of predictions	Probability of success (%)(P)
$ModNN_1$	92	3	5	2	3.2
$ModNN_2$	80	4	5	1	5.0
$ModNN_3$	81	1	5	4	1.2

As the next step of the algorithm, we need to consider pairs of models. For each model, it is necessary to count the number of realized forecasts, the number of justified and unjustified forecasts, and also calculate the probability of justification for each pair. Let us introduce the following notation – $P_{i,j}$ $P_{i,j}$ this is the probability of the forecast intersection being justified $ModN_i$ and $ModN_j$. The following table shows these values (see **Table 7**):

Table 7: *Probabilities success of a combination of forecasts in the case of " unnecessary" models .*

$P_i \cap P_j$	P_1	P_2	P_3
P_1		5	6
P_2	5		3
P_3	6	3	

From Table 7 we can conclude that the intersection of two unnecessary models leads to an "almost sufficient" model.

This way we can use "unnecessary" models if we select "unnecessary" models from models of forecasting with a certain filter. It is possible to use "unnecessary" models in some positions, because the intersection of unnecessary models can give us "almost sufficient" models.

IV. Discussion

We explained what "necessary" and "sufficient" models are. For "unnecessary " models, an algorithm is given for how to choose a hybrid model - the intersection of two or more models that together give a forecast with a higher probability. We also discussed "sufficient" models and an algorithm for selecting such "sufficient" models, the combination of which completely covers all past events, that is, the combination of such "sufficient" models becomes "necessary".

Discusses how one can obtain a "sufficient" or "nearly sufficient" forecasting model by combining "necessary" models, and by combining "sufficient" models to obtain a "necessary" or "almost necessary" model.

In our earlier work, these models were not taken into account; such models were removed from the model database. Similarly, when considering "sufficient" models, if the forecast of the occurrence of an event is specified redundantly, such a model can be excluded from the set of "sufficient" models.

From "sufficient" models we obtain the "necessary" model, which will be both "sufficient" and "necessary" at the same time. In addition, we combine enough models to get the "necessary" model.

All of this uses forecast statistics to strategically select a hybrid model.

THE MANAGEMENT OF NATECH EVENTS IN SEVESO SITES FOR THE CASE OF FLOOD RISKS

Romualdo Marrazzo
•
ISPRA - Istituto Superiore per la Protezione e la Ricerca Ambientale, Roma, ITALY
romualdo.marrazzo@isprambiente.it

Abstract

The Seveso III Directive 2012/18/EU imposes an obligation for the site operator to identify the major risks of the establishment, taking also into account technological accidents such as fires, explosions, and toxic releases that can occur following natural disasters (so-called NaTech risks). Floods, which are amplified by climate change, are among the most widespread natural dangers in European countries. The Safety Management System for the Prevention of Major Accidents in Seveso Sites is important in ensuring the correct implementation of the prevention and protection measures against major accidents originating from these events, with specific procedures for extreme weather conditions. Starting from the main outcomes of the analysis of industrial accidents, where floods have been identified as a significant and triggering cause, a specific focus is then presented on the main types of plants, infrastructures, and industrial equipment vulnerable to extreme weather conditions. These lessons learned are also useful examples of how organizations could manage these problems, through specific procedures, good practices, and methods used to assess the industry's response to NaTech issues. A practical case of application of safety evaluations has therefore been reported for a type of industrial plant that is particularly relevant on the Italian territory, namely the underground storage of natural gas. The risks of floods are particularly relevant because of the extension of these plants over large areas, which means that parts of them can pass through areas subject to flooding. Finally, the article describes an in-depth analysis carried out on the NATECH risk of flooding for industrial plants, starting from the Italian technical regulation, with details to be considered in the risk assessment for the identification of the critical elements for safety, as well as the main prevention and protection measures for equipment.

Keywords: Seveso, SMS, procedures, NATECH, events, flood

I. Introduction

The Seveso III Directive 2012/18/EU, implemented in Italy by the D.Lgs. 105/2015 [1], imposes an obligation for the site operator, in identifying the hazards and assessing the major risks of the establishment, to take the NATECH risks into account, paying attention to the entire spectrum of natural hazards that may affect the site. With the term NaTech, the international literature identifies technological accidents, such as fires, explosions, and toxic releases that can occur inside industrial establishments and along distribution networks and pipelines following natural disasters.

The evaluation of the effects of natural events on Major Accident Hazard establishments requires a systemic and multidisciplinary approach concerning the complexity of the contexts to be analyzed both from the plant and structural point of view. The methodological approach for assessing the NATECH risks of Seveso sites must be based on meeting the objectives underlying the regulatory text, which consist of preventing major accidents connected to the presence of dangerous substances and limiting their consequences for human health and the environment.

It is therefore considered necessary, with this paper, to provide support for the evaluation of the implementation of the Safety Management System for the Prevention of Major Accidents

(SMS-PMA) during the control activities on Seveso establishments, with specific attention to the checks to be carried out during inspections regarding the NATECH risks, according to the D.Lgs. 105/2015.

II. Methods

The incidental data extracted from the e-MARS database of the European Commission show that from 1985 to today in the EU countries, there has been an average NATECH accident per year, while about 7000 accidents that occurred in industrial sites, collected in the Bank UK-HSE MHIDAS data [2], 3% of accidents are classified as NATECH having been induced by natural events such as earthquakes (8%), floods (16%), landslides (7%), strong winds (13 %) and lightning (56%). Fig. 1 is shown below, which represents the number of accidents occurring as a function of extreme natural events [3].

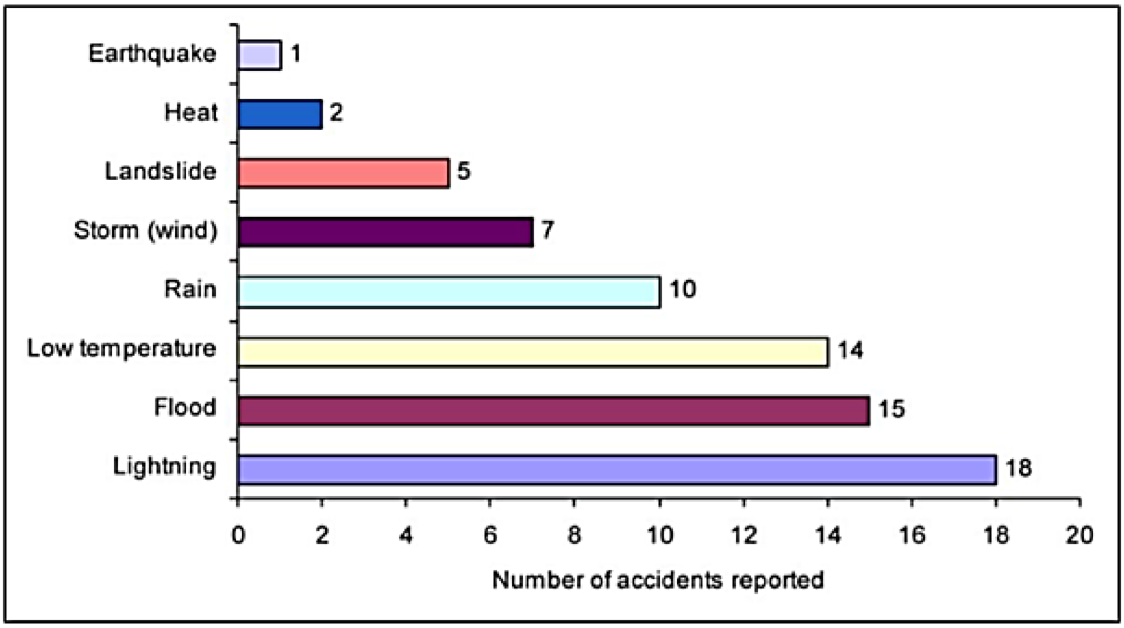

Figure 1: *Number of accidents occurring as a function of extreme natural events*

In Table 1 below it is possible to summarize the main types of plants, infrastructures, and industrial equipment vulnerable to natural hazards in the event of adverse weather conditions.

Table 1: *Equipment and plants vulnerable to natural hazards*

Industrial equipment and plants	Natural hazards for adverse conditions
Gas, fuel oil, and coal thermoelectric power plants	Floods
Pipelines for the transmission and distribution of gas, oil pipelines	Floods (Landslides)
LPG depots	Floods
Mineral oils depots	Floods, lightning, strong winds, storms
Refineries and chemical and petrochemical plants:	
Process columns	Strong winds, storms
Above ground tanks	Strong winds, storms, floods, lightning
Mounded tanks	Floods
Pipelines (also underground)	Floods
Motors, pumps, compressors	Floods

Control room and instrumentation	Floods, lightning
Warehouses of packed products	Floods
Service utilities commonly found in industrial plants whose failure can lead to hazardous situations: boilers; refrigeration systems; cooling towers; power supply; water treatment; torch systems	Strong winds, storms, floods, lightning, changes in water availability, increases in water temperatures, and decreases in availability of cooling water
Toxic products depots	Floods
Warehouses of phytosanitary products	Floods
Coastal depots, plants, and terminals	Sea storms, sea level rise

I. Floods

As indicated in Table 1, floods (which in turn may or may not be a direct consequence of the occurrence of earthquakes), with consequent landslides (depending on the terrain) are the most widespread natural danger in our country, and many productive activities in all sectors are vulnerable in the event of adverse weather conditions.

The danger of floods can never be eliminated and therefore every manager of a Seveso establishment must prepare in advance to limit the impact that a flood could have on its activities, through dedicated planning that considers that an event of this type could trigger or make a major accident more serious, directly or indirectly.

He must therefore provide, through the adaptation of its SMS-PMA (Safety Management System for the Prevention of Major Accidents), the necessary measures to prevent or limit the consequences for human health and the environment.

Directive 2007/60/EC relating to the assessment and management of flood risks (Floods Directive - FD) [4], provides the elements for the assessment and management of this type of risk which in Italy is implemented with D.Lgs. 49/2010 [5].

II. Industrial accidents following floods

Following continuous torrential rains which lasted several days, the plants of a refinery located in the port area flooded (Mohammedia refinery in Morocco in 2002). Production was stopped due to the water level. A violent fire followed, as well as several explosions of tanks, electrical equipment (transformers), and pipes. Four hours later, fires persisted in the gas and crude oil sectors of the refinery. The fire was extinguished after 20 hours. Two people died and four were injured. Extensive material damage resulting from the accident led to the closure of the refinery and the suspension of all activities.

The sequence of fires was caused by the flood that moved the exhausted oil, displacing it from the sewer system. The waste oil that floated on the surface then encountered the hot parts of the systems, causing several fires and explosions in the pipes and electrical transformers. From the above it is fundamental:

- Implement effective procedures to prevent the rapid distribution of flammable liquids by alluvial waters;
- Good maintenance practice is to make sure the drains are clean so that they don't block the water drain.

The site manager, to mitigate the impact of a flood, must undertake a series of improvement actions to make the perimeter of the plant, buildings, or specific areas within buildings or equipment containing hazardous substances (in quantities and conditions such as to cause a major accident), inaccessible to water.

These actions include the following types of protection (or combinations thereof): Construction of defense works (structural measures, such as embankments, drainages, stabilization, roofing); Closure of openings and water entry points; Waterproofing of walls; Seal the penetrations in the walls; Installation of pumps for the collection and removal of water (dewatering pumps); Installation of non-return valves; Ensure a control plan periodically and be carried out afterward a flood and before an expected flood.

The site manager should also locate fire pumps, sprinklers, suppression systems, and other fire suppression systems, with associated electrical equipment, outside of flood hazard areas or above the maximum achievable water level.

If there is critical equipment for process safety, production, or operations that are located at a lower level than the maximum achievable by the water, the site manager must ensure they are flood-proof (if their functionality is required during the flood for safety reasons or to ensure continuity of production). In the case of electrical equipment, it must be designed to work even if continuously immersed and have an electrical classification IP X8 (protected by permanent immersion in water - submersible to 3 m depth in continuous immersion and in any case for more than one hour, resistant to a pressure of at least 10 bar exerted in all directions).

III. Results

I. The case of underground natural gas storage as strategic assets

The underground natural gas storage are located in depleted underground deposits of the same mineral. The storage of natural gas is an industrial process that consists of injecting gas into an underground rock system, to guarantee its accumulation and subsequently supply it in a second phase, to face a market demand or to face situations of lack/reduction of supply. Storage therefore play a strategic function for national energy reserves, being considered strategic assets for the Italian industry.

In summary, the process in which natural gas intervenes is represented by two phases that alternate during a year of operation:

- The phase of injection of gas through wells, in the spring-summer period, which consists of storing the natural gas coming from the network transport in the field through the wells after compression
- The gas supply phase, in the autumn/winter period, during which the gas is supplied, dehydrated, treated, and redelivered to the transport network.

The main areas involved in the process concern: reservoirs, wells and cluster areas, compression plants, treatment plants, and pipelines. Twelve underground natural gas storage sites are in Italy, operating in five different regions in the central north of the country [6].

To provide technical support for the assessment of the safety reports of underground natural gas storage establishments, pursuing a uniform assessment throughout the national territory, also given the peculiarity of these establishments, the Guidelines "Underground storage of natural gas - Guidelines for the evaluation of Safety Reports", issued in October 2018 [7] were drawn up by a Working Group set up by the Italian National Authorities involved in industrial control activities on Seveso establishments. The Guidelines deal in depth with the issue of risk analysis, and also include NaTech risks of floods, based on a national overview of the Safety Reports presented by the site managers of the underground natural gas storage.

Finally, the Internal and External Emergency Planning for NaTech events must necessarily consider that such events may involve a plurality of contemporary emergencies, the interruption of electrical and telephone lines and communication routes. It is therefore necessary to implement and deepen these aspects in emergency planning, taking care of the training of both plant personnel and external intervention structures.

II. NaTech Risk Assessment in Underground Natural Gas Safety Reports

A complete NaTech risk analysis consists of the following steps:

- Preliminary analysis, carried out through territorial contextualization, historical analysis of natural events, and assessment of the hazards of each NaTech event considered for the site
- Identification of equipment exposed to risk

• Identification of prevention and mitigation measures, possible estimate of occurrence frequencies and areas of damage, relative integration of the scenarios in the Safety Report

Based on the Safety Reports examined, the site Managers completed the first of the phases indicated; in some specific situations, the second phase and part of the third phase have also been completed, as requested by the Competent Authorities, identifying the prevention and mitigation measures. Based on the safety reports examined, the technical assessment of the scenarios still must be faced. Given the relevance of the NaTech risk of floods, because of the extension of these plants over large areas, which means that parts of them can pass through areas subject to flooding, particular attention has been paid to the hydrogeological risks.

III. The evaluation of the hydrogeological risks

Natural gas storage, compared to other types of establishments, have the peculiarity of insisting on vast territories belonging to municipalities, provinces, and sometimes even different regions, as they consist of compression and treatment plants, pipeline connections, well areas, cluster areas, and related equipment.

It can be stated that it is not uncommon for a part of the plants to be in areas subject to risk of hydrogeological instability and flooding, as identified by the sector planning tools, prepared by the competent district basin authorities for the area. In some cases, although the risk maps didn't cover specific areas, the plants were affected by instability and flooding phenomena, based on the data deriving from the analysis of the historical experience gained and from the consultation of specific databases.

In the implementation of the Seveso III Directive, attention was paid to also carrying out the analysis of technological risk induced by instability and flooding. To date, also thanks to the indications contained in the Guidelines, the Companies have produced an in-depth analysis of the risk of damage to equipment and piping because of instability or flooding. The following paragraphs indicate the methodologies that have been applied to assess these risks, their limits, and the margins for improvement.

IV. Failure risk analysis

In situations in which the plants and pipes are in areas subject to hydrogeological instability, specific studies were requested from the Site Manager, also following the indications of the Guidelines, for the evaluation of risk and planning intervention actions to mitigate it.

The studies produced have addressed the problem in the way described below. The available bibliographic studies on the geological, geomorphological, and hydrogeological structure of the study area were first described. Investigations were carried out on the seismicity of the territory on a local scale. The pipeline routes and plant areas were reported on the thematic maps drawn up by the competent Basin Authorities. The study was therefore carried out through careful surveys in the field, extended to all plant areas and along the connecting pipelines, with particular attention to the areas affected by criticalities even if not registered by the territorial planning tools. The predisposing factors for the establishment of conditions of instability (morphological configuration, geo-lithological nature of the sediments present) and the determining factors (periods of intense precipitation) were therefore identified. The surveys carried out were promptly reported in synoptic cards, accompanied by extensive photographic documentation, and then reported on detailed thematic maps.

The main problems highlighted were:

• Areas subject to erosion. For the areas subject to erosion, areas with surface erosion on slopes denuded by vegetation cover and areas subject to river erosion, in turn, distinguished between bottom or bank erosion, were distinguished

• Areas subject to slope instability. The areas with problems relating to the stability of the slopes have been divided according to their degree of danger to the integrity of the pipelines, distinguishing the following types: Active landslide, Quiescent landslide, stabilized landslide, surface landslide, widespread instability

The analysis and survey activity highlighted various areas with articulated morphologies, which indicate a certain propensity for the slopes to fall apart. Some of these situations were considered "to be monitored over time", to detect any changes.

In the areas of fluvial relevance, problems have been found in progress, following the erosive actions carried out by the waterways. For these problems, the Company has prepared and implemented structural interventions consisting of moving the pipelines or restoring the bank. For each area, the Company has defined the interventions and checks to be carried out, considering the situation observed, to safeguard the integrity of the conduct and to follow any developments in the failures.

The mentioned periodic monitoring activities have been included in the Safety Management System and are subject to verification during the inspections provided for the D.Lgs. 105/2015. Periodically, following the monitoring activities, the Company communicates to the Competent Authorities the planning of improvement, consolidation, and restoration interventions, with all the necessary authorizations from the bodies in charge. The Site Manager has also identified prevention/mitigation measures, consisting in the interception of equipment and pipes in the areas at risk, in the event of a weather alert.

The methodology chosen certainly constitutes a starting point for the analysis and management of the risk deriving from failures.

In situations that need more attention, a possible action for improvement can be identified in associating visual monitoring with instrumental measurements aimed at quantifying any landslides. In fact, in this way, it will be possible to identify attention limits, so as to guarantee the persistence of security conditions. Further actions can be carried out, such as intensifying monitoring and carrying out stability checks of the slopes, in case of more severe conditions.

If the results of the further actions indicated above shows situations of increased risk above "acceptable" values, without prejudice to any mandatory provisions implementing in the planning tools, it will be necessary to plan structural interventions aimed at guaranteeing the stability of the plants. Typical examples are:

- Construction of consolidation and stabilization works for risk mitigation, after a hydrogeological compatibility study and approval by the competent Authorities
- Delocalization of pipes and systems

A further aspect of improvement is the in-depth study of the accident scenarios resulting from instability, by evaluating the probability of loss of containment, subsequent ignition of the released gas and calculation of the areas of damage.

V. Hydraulic risk analysis: the consideration of flooding

For plants and structures located in areas at risk of flooding, the site Managers were asked to carry out a specific risk assessment. The study produced was of a multidisciplinary type and started from field surveys in all plant areas and along the connection network falling within areas even if not recorded by the territorial planning tools. In particular, the following activities were preliminarily carried out:

- Survey for the topographical definition of the study area.
- Geo-gnostic and geophysical investigations campaigns aimed at the stratigraphic, hydrogeological and seismic reconstruction of the study area. These studies make it possible to identify the characteristics of the subsoil and the seasonal groundwater levels.
- Vegetational surveys and development of the relative cartography.
- Bibliographic studies of the geological, geomorphological and hydrogeological structure of the study area, supplemented by hydro-morphological survey activities in the field to apply the IDRAIM (Italian acronym for "Hydromorphological evaluation system, analysis and monitoring of watercourses") methodology [8]. This methodology is aimed at understanding the aspects of fluvial dynamics of the watercourses and at the classification of areas most dangerous due to erosion by the watercourses, providing an overall picture of the hydro-geomorphological evolution processes.

- Detailed hydrological-hydraulic studies for the hydrographic areas. These studies make it possible to analyze the flooding problem in correspondence with the plant areas, carrying out a detailed hydraulic study to determine the water tie rods with a return period of 200 years.
- Evaluation of erosive phenomena at the bottom of the riverbed, in correspondence with river areas where the crossing of the watercourse by operational methane pipelines is detected.

The mentioned activities allowed a complete view of any hydraulic criticalities that could affect the surface systems. Once the plants located in the areas at risk of flooding have been identified, the study analyzed the as-built documentation relating to the plant areas concerned, studying the characteristics of the foundations, the equipment present and the ground, and specifically: dimensions of the foundations; depth of the laying surface; characteristics of the material constituting the foundations: weight of equipment; diameter and thickness of the pipes; depth of burial; characteristics of the pipe's material; weight of the pipes; soil characteristics.

This detailed analysis, aimed at acquiring all the necessary information relating to the Cluster areas, well areas, and connections, proved to be functional to the verification of the hydrostatic thrusts for the equipment and pipelines.

The risk analysis was completed through geotechnical, load bearing, and lifting capacity checks, for the foundations of the equipment involved and for the sections of pipelines that are potentially floodable or with the presence of seasonal groundwater above the pipeline. A bearing capacity analysis of the foundations was also performed as required by the Technical Standards for Construction. If the checks relating to the buoyancy thrusts and the analysis of the bearing capacity in the event of flooding were not satisfied, without prejudice to any mandatory provisions, it would be necessary to plan structural interventions.

These interventions are aimed at guaranteeing the stability of the structures and the absence of containment losses in the event of flooding, also considering the ongoing climate changes, which make intense and sudden phenomena more and more frequent. They may consist in the relocation of the plants to areas outside those of risk or in interventions to make the structures safe, after a hydraulic compatibility study and approval by the Competent Authorities. Also, for the risk of flooding, as for the seismic and instability risk, the risk analysis carried out up to now by the Site Manager can be completed with the analysis of the accident scenarios resulting from flooding.

IV. Conclusions

The results of the NATECH risks assessment must be considered in the location, design, construction, and operation of the industrial establishment, as well as in the implementation of mitigation measures and emergency planning. The site operator of industrial establishments under the Seveso directive should develop appropriate measures to address natural hazards, to allow the maintenance of control of the plants vital to safety and their safe operation.

In this sense, the Safety Management System for the Prevention of Major Accidents, and the relative integration with the operational management of the establishment, plays an important role in ensuring the correct implementation of the prevention and protection measures against major accidents originating from NaTech events, with specific procedures for extreme weather conditions, such as heavy rainfall, lightning, strong winds and extreme temperatures.

Starting from the main outcomes of the analysis of some industrial accidents, where natural hazards have been identified as a significant and triggering cause, it is possible to focus the main types of plants, infrastructures, and industrial equipment vulnerable to extreme weather conditions. These lessons learned are also useful examples of how organizations could manage these problems, through specific procedures, good practices, and methods used to assess the industry's response to NaTech issues.

In this framework, the technical evaluation of NaTech risks of underground natural gas storage, as national strategic assets for the national supply of energy sources within the diversification policies, is of particular importance. In addition to the peculiarity of using a natural reservoir for storage, they also extended over large areas, as they consist of multiple plants joined by pipelines (compression and treatment stations, well areas, cluster areas). The characteristics of the activity made it necessary to draw up a Guideline for the assessment of safety reports, focusing attention on natural events or disasters that can induce one or more technological accidents such as fires, explosions, and releases, with particular attention to hydrogeological risk.

The extension of these establishments over large areas means that parts of the system, and particularly the connecting pipes, can cross areas subject to instability and flooding. The analysis conducted in the safety reports has certainly made it possible to focus attention on the problems present; the assessment must be completed with the study of possible accident scenarios deriving from natural risks of floods, to adopt the necessary measures for the prevention, mitigation and management of the emergency.

RISK-ORIENTED APPROACH TO THE RECONSTRUCTION OF RESIDENTIAL BUILDINGS AND STRUCTURES IN THE ARCTIC ZONE

Azariy Lapidus, Alan Khubaev, Tembot Bidov, Roman Samsonov
•
National Research Moscow State Construction University, Moscow, RUSSIA
KhubaevAO@mgsu.ru

Abstract

The report is dedicated to the study of various approaches in regards to the reconstruction of residential buildings and structures in the Arctic zone using a risk-based approach. The aim of the research is to develop methods that take into account the specific climatic and geological conditions of the Arctic in view to minimising risks in the design and construction works. The objective of the study includes the following (i) analysis of existing methodologies, (ii) assessment of their applicability in Arctic conditions and (iii) development of new approaches that take into consideration the regional specificities. The relevance of the topic is due to the growing interest in the development of the Arctic and the need to ensure the safety and comfort of living in harsh climatic conditions.

The study uses data on climatic and geological peculiarities of the Arctic zone, as well as modern methods of risk analysis. Modelling and forecasting methods have been applied to assess the impact of various factors on the stability and durability of buildings. Expert judgements and empirical data from research and monitoring of existing construction projects in the Arctic have also been used.

The results of the study have shown that the application of a risk-based approach can significantly improve the reliability and safety of reconstructed buildings in the Arctic zone. Key risk factors were identified, such as interalia geotechnical risks, risks of heat losses and energy efficiency of buildings, specificity of building materials, risks in adapting to changing climate, transport and logistics. An algorithm for calculating the degree of risks in the reconstruction of buildings and structures in the Arctic zone was designed accordingly, which includes 4 actions. The formula for assessing the degree of risks in reconstruction in the Arctic zone is developed. Weight characteristics of each risk factor are determined by the method of expert evaluations. Variation of each risk factor at three levels: unsatisfactory, good, excellent is performed. An adapted scale for qualitative assessment of the degree of risk in reconstruction in the Arctic zone was also developed.

The details of the obtained results have an important practical significance for construction and reconstruction of facilities in the Arctic. This implies that the recommendations can be used in the design and planning of construction works, which will reduce the probability of accidents, risks and hazards, thus increase the durability and life span of buildings. The implementation of the proposed methods shall largely contribute to the sustainable development of infrastructure in the Arctic zone, hence ensuring the safety and comfort of living.

Keywords: Arctic, reconstruction, residential buildings, risk-based approach, climatic conditions, geological features, wind loads, construction technologies, efficiency improvement

I. Introduction

The Russian Federation has significant territories in the Arctic region, and therefore development and research in this area is challenging to the Russian Federation. The Arctic zone comprises of extensive natural resources, including oil, gas, mineral wealth and fish. Infrastructure development and residential renewal are becoming crucial for attracting investment and creating a favourable economic background. The Arctic has significant potential for development and research aimed at improving the comfort of human habitation in this climatic zone [1-3].

The Arctic region is currently undergoing a gradual transformation in the context of global climate change which will cause this location to become a centre of intense change. Given the fact that this unique region, known for its distinctive climate, is undergoing significant transformations, same will as a result affect all aspects of its existence. Against this background, special attention is being given to residential structures, which face the dual challenge of maintaining their functionality and efficiency in order to cope with the increasing warming of the Arctic region, as well as adapting to the potential threats posed by these changes [4-6].

The unique climatic conditions of the Arctic zone, such as fluctuating temperatures, regular snowfalls, high winds and changes in permafrost conditions, affect residential buildings, making them more vulnerable and requiring comprehensive solutions to maintain their functionality and safety. These atmospheric conditions can cause significant damage to wall cladding materials, roofing and windows, making it necessary not only to modernise but also to change building standards to meet the new Arctic conditions. In this regard, the issue of reconstruction of buildings and structures becomes even more urgent with the active development of Arctic territories and the increasing need for housing [7,8].

Reconstruction of buildings and structures in turn helps to solve the problem of providing people with comfortable and safe housing. Our participation in the research on reconstruction in the Arctic zone gives Russia an opportunity to become actively involved in the design of updated standards, norms, guidelines and regulations in the region. The development of innovative technologies and solutions will subsequently strengthen the country's position as a key participant in international cooperation and partnership in the Arctic area [9].

The purpose of this research is to study the peculiarities of reconstruction of residential buildings in the Arctic zone under the conditions of modern climatic changes, as well as to identify ways and means to reduce risks related to the organisation of reconstruction work on buildings and structures.

Taking into consideration the gradual warming of the Arctic region, and its impact on the overall building structure as well as the technical issues associated with permafrost thawing and extreme weather events, it will be our responsibillity to detect, diagnose and identify these specific problems. Consequently we will propose new approaches to organising reconstruction works aimed at improving the sustainability of residential buildings in this region.

The main direction of the scientific research is to develop a risk-oriented approach to the reconstruction of residential buildings and structures in the Arctic zone. It differs significantly from the current understanding of the problem [10-12]. This approach complements and deepens the already known methods, offering new solutions to improve the stability and durability of buildings in a changing climate [13-15].

In addition, the article introduces new facts, conclusions and recommendations based on the conducted research. The obtained results have an important practical significance and can be used in the design and planning of construction works, which will reduce the probability of accidents and increase the durability of buildings.

The purpose of this report proceeds from the scientific problem and consists in the study of the peculiarities of reconstruction of residential buildings in the Arctic zone using a risk-oriented approach [16]. Methods that allow taking into account specific climatic and geological conditions of the region are thoroughly discussed in this report, and innovative solutions are being proposed to mitigate risks in the design and construction works. This study will serve as a basis for the development of a comprehensive methodology to improve the efficiency of the organisation of reconstruction of buildings and structures in the conditions of the far north and the Arctic zone of the Russian Federation, based on neural modelling. The use of modern information technologies and artificial intelligence will significantly improve the quality of management and planning processes in the reconstruction of buildings and structures [17-19].

II. Methods

In the Arctic region, where climate and natural conditions pose specific risks for residential renovation, an in-depth study of the problems and the development of effective strategies and technical solutions are required. By analysing the main types of risks, such as geotechnical risks, heat losses, building material features, adaptation to changing climate and transport and logistics risks, ways to address them have been identified.

The table laid down below gives a comprehensive view of the risks and the corresponding solution strategies. Each category of risks is described in more details, thereafter the main areas of technical solutions are presented. This analytical approach outlines the main risks in reconstruction in the Arctic zone and identifies strategic methods to effectively address these technical risks.

Table 1: *Risks and solutions for reconstruction in the Arctic zone.*

№	Name of risk	Description	Solutions
1	Geotechnical risks	In Arctic permafrost conditions, ground thawing can lead to deformation of foundations and walls of buildings. This creates the need to develop special geotechnical solutions aimed at stability and prevention of deformations due to changes in frozen soils.	Permafrost thawing: Develop engineering methods to stabilise frozen ground, such as freezing technologies. Introduction of freezing systems that use refrigerants to keep the ground stable. Foundation deformations: Application of pile foundations to account for changes in frozen soils. Investigation of optimal pile depth and pile location parameters to minimise the impact of permafrost thawing.
2	Heat loss risks and energy efficiency of buildings	The Arctic zone is characterised by low temperatures, which causes the problem of heat loss in buildings. Efficient insulation and innovative heating technologies become important to maintain comfortable conditions inside the dwelling and reduce energy consumption.	Innovative insulation: Development and use of new thermal insulation materials such as vacuum panels and thermal insulation coatings. This will help to reduce heat loss and ensure efficient heat retention in buildings. Heating technologies: Introducing heat pumps and thermal storage technologies to provide an efficient heating system capable of maintaining comfortable conditions in cold climates.
3	Specificity of construction materials	Traditional building materials may not be able to cope sufficiently with the Arctic climate. For example, moisture freezing in the structure of walls can cause damage. The development and use of specialised	Heat resistant materials: Development of building materials capable of maintaining structural integrity at low temperatures and preventing moisture from freezing inside walls. Introduction of new formulations resistant to arctic conditions. Use of composites: The use of composite materials that combine strength with

		building materials that are resistant to low temperatures is becoming an important aspect of reconstruction.	thermal insulation properties to create more resilient structures in Arctic conditions.
4	Risks in adapting to a changing climate	Projected changes in the climate, such as increasing temperatures and the frequency of extreme weather events, require the development of buildings that can adapt to variable conditions. This includes strengthening structures, improving drainage systems and adapting to new building standards.	Reinforcement of structures: Developing structures that can withstand high winds, snowfall and other extreme weather conditions. Strengthening structural elements of buildings to increase their resilience to variable conditions. Drainage Improvements: Designing effective water collection and drainage systems to prevent the negative effects of snow and ice melt on roofs and around foundations.
5	Transport and logistics	The remoteness and inaccessibility of the Arctic territories create difficulties in the delivery of construction materials and equipment. Logistical problems can significantly increase costs and complicate the reconstruction process.	Local production bases: Establish local production bases for building materials, reducing dependence on long-distance supplies and simplifying logistics. Delivery technologies: Introduce delivery technologies such as drones or mobile warehouses to deliver materials and equipment to remote areas more efficiently and reliably.

In the context of residential building renovation in the Arctic zone, facing technical challenges requires not only engineering solutions, but also careful analysis, evaluation and process optimisation. Based on the results of the study, key challenges have been highlighted:

- Geotechnical risks
- Heat loss risks and energy efficiency of buildings
- Specificity of construction materials
- Risks in adapting to a changing climate
- Transport and logistics

In order to achieve our goal, it is necessary to solve the tasks, approaching it in a systematic way. This approach requires not only traditional engineering solutions, but also the introduction of modern technologies.

III. Results

One of the contemplated areas of state-of-art technology is the use of neural modelling for real-time prediction, optimisation and decision making. Neural networks have proven their effectiveness in a variety of areas including data analysis, process optimisation and forecasting. The application of neural modelling can play a key role in addressing the identified risks presented in our table, providing accurate and adaptive approaches to complex engineering problems.

Such an integrated approach, combining traditional engineering methods and neural modelling capabilities, can improve the efficiency, accuracy and sustainability of reconstruction processes in the Arctic zone. The following table systematises the problems and solutions and assesses the feasibility of applying neural modelling in each area.

Table 2: *Ways to predict and address risks using neural modelling.*

Risks and Aspects	Solutions	Neural modelling capabilities
Geotechnical risks	- Development of technical solutions for stabilisation of frozen soils. -Application of pile foundations taking into account changes in frozen soils.	Prediction of ground deformations and optimisation of foundation parameters based on data on local climatic conditions.
Heat loss risks and energy efficiency of buildings	-Development of new thermal insulation materials. - Introduction of heat pumps and heat storage technologies.	Optimisation of heating and ventilation systems using neural networks to adapt to changing temperatures.
Specificity of construction materials	- Development of building materials resistant to low temperatures. - Use of composite materials.	Analysis of material properties, prediction of their behaviour under Arctic climate conditions.
Risks in adapting to a changing climate	- Strengthening of structures. - Improvement of drainage systems.	Prediction of extreme weather conditions and optimisation of structural changes in buildings.
Transport and logistics	-Creating local production bases. -Use of delivery technologies.	Optimisation of logistics networks and prediction of optimal routes for material delivery

The result of the study is the formed algorithm for calculating the degree of risks in the reconstruction of buildings and structures in the Arctic zone, which includes 4 actions: analysing and assessing risks; correlating the risk factor with Table 4, determining the quantitative value of risk according to Formula 1, determining the qualitative value of the degree of risk according to Table 5. In order to assess the degree of risk, we can use a mathematical apparatus to quantify the degree of risk. The formula for assessing the degree of risk in reconstruction in the Arctic zone can be presented as follows:

$$R = (W1 \times F1 + W2 \times F2 + \cdots + Wn \times Fn) \quad (1)$$

Where:

R - risk level

Wi - weighting factor for each risk factor

Fi - value of each risk factor

Each risk factor will be assigned the following designations: F1-Geotechnical risks, F2-Risk of heat loss and energy efficiency of buildings, F3-Specificity of building materials, F4-Risk in adapting to a changing climate, F5-Transport and logistics.

The next stage of the study was to determine the weighting characteristics of each risk factor using the expert judgement method. The method of expert judgement allows to create a certain collective consciousness formed from the opinion of a group of experts. This approach is more effective than the opinion of a single person.

In our case, expert analysis can be used to determine the weighting of factors. The experts participating in the study were included in the national register of specialists. This fact allowed us to judge about the competence of experts and their extensive experience in the field. Upon completion of the experts' questionnaires, data processing was carried out. The results were plotted in a graphical form for better visualisation and understanding, a histogram of factors with the minimum limit of significance of factors was built.

Weighting factors: W1 = 0,3 (Geotechnical risks); W2 = 0,2 (Heat loss risks and energy efficiency of buildings); W3 = 0,2 (Specificity of construction materials); W4 = 0,15 (Risks in adapting to a changing climate); W5 = 0,15 (Transport and logistics)

In Table 3, each of the risk factors is represented as one of three alternatives: unsatisfactory, good, excellent. In order to further use these qualitative characteristics in the form of quantitative ones, the concept for unsatisfactory 0,3, for good 0,5, for excellent 0,8 was introduced.

Table 3: *Varying organisational and technical factors.*

Risk factor	unsatisfactory- 0,3	good-0,5	excellent – 0,8
Geotechnical risks	-Frost thaw does not exceed 10% of the total area of the construction site. -Foundation deformations do not exceed 5% of the total building height.	-Melting of permafrost does not exceed 5% of the total area of the construction site -Foundation deformations do not exceed 2% of the total building height.	-Frost thawing is absent or does not exceed 1% of the total area of the construction site. -Foundation deformations are absent or do not exceed 1% of the total building height.
Heat loss risks and energy efficiency of buildings	-Heat losses through walls and roofs do not exceed 20% of the total heat load of the building. -Energy efficiency of heating and air conditioning does not exceed 10% of the total energy consumption of the building.	-Heat losses through walls and roofs do not exceed 10% of the total heat load of the building. -Energy efficiency of heating and air conditioning does not exceed 5% of the total energy consumption of the building.	-Heat losses through walls and roofs are absent or do not exceed 5% of the total heat load of the building. -Energy efficiency of heating and air conditioning is absent or does not exceed 2% of the total energy demand of the building.
Specificity of construction materials	-Resistance to low temperatures does not exceed 50% of the total area of the building materials. -Resistance to wind loads does not exceed 30% of the total area of the building materials.	-Resistance to low temperatures does not exceed 70% of the total area of the building materials. -Resistance to wind loads does not exceed 50% of the total area of the building materials.	-Resistance to low temperatures is absent or does not exceed 90 per cent of the total area of the building materials. -Resistance to wind loads is absent or does not exceed 70 per cent of the total area of the building materials.
Risks in adapting to a changing climate	-The increase in temperatures does not exceed 2°C from the average temperature over the last 10 years. -An increase in the frequency of extreme weather events does not exceed 10 per cent of the average frequency over the last 10 years.	-The increase in temperatures does not exceed 1°C from the average temperature over the last 10 years. -An increase in the frequency of extreme weather events does not exceed 5% of the average frequency over the last 10 years.	-Temperature increase is absent or does not exceed 0.5°C from the average temperature over the last 10 years. -An increase in the frequency of extreme weather events is absent or does not exceed 2% of the average frequency over the last 10 years.
Transport and	-Accessibility to the construction site does	-Accessibility to the construction site does	-Accessibility to the construction site is absent

logistics	not exceed 50% of the total construction site area.	not exceed 70% of the total construction site area. -Transport problems do not exceed 10% of the total area of the construction site.	or does not exceed 90% of the total construction site area. -Transportation problems are absent or do not exceed 5% of the total construction site area.

One of the most convenient ways to construct an integral indicator is the generalised Harrington desirability function. This function is based on the transformation of natural values of private indicators of different physical nature and dimension into a single dimensionless scale of desirability (preference). We adapted this scale to our obtained data, and the adapted scale was summarised as detailed in the table below (Table 4).

Table 4: *Adapted scale of the degree of risk.*

Risk level R	Risk assessment
Low risk	R < 0,39
Medium risk	0,4 ≤ R ≤ 0,6
High risk	R > 0,61

This range allows us to assess the degree of risk qualitatively. Low risk: the degree of risk is below 0,39 which indicates that the risk is minimal and does not require special attention. Medium risk: the degree of risk is between 0,4 and 0,6 which means that the risk is moderate and requires some attention and appropriate measures to minimise it. High risk: the degree of risk is above 0,61 which shows that the risk is high and requires serious attention and urgent measures to minimise it.

IV. Conclusions

The research conducted on the topic of risk-based approach in the reconstruction of residential buildings and structures in the Arctic Zone has highlighted key aspects that influence the efficiency and success of the reconstruction process in an extreme climate. The main results of the research are presented below:

- The study confirmed the urgency of the problem of reconstruction of residential buildings in the Arctic zone, especially in the context of a changing climate and warming.
- The study highlighted the technical challenges faced by engineers in reconstruction in Arctic conditions, such as: geotechnical risks, heat loss risks and energy efficiency of buildings, specificity of construction materials, risks in adapting to the changing climate, transport and logistics.
- An algorithm for calculating the degree of risks in the reconstruction of buildings and structures in the Arctic zone was formed.
- An approach to the assessment of reconstruction efficiency is developed, including criteria of satisfactory, good and excellent performance for the main factor.

Abstract

Earth remote sensing (ERS) is one of the most important and rapidly developing types of space activities, which is most susceptible to innovation. It ensures the rapid receipt of practically significant results, which are already making a major contribution to the economy of developed countries of the world. This sector of space activity is based on the use of high science-intensive technologies and the latest achievements of fundamental and applied science. Space information is used in many areas, primarily for preventing and eliminating the consequences of natural disasters and man-made accidents, research and rational use of natural resources,environmental protection, energy, urban planning, transport complex, meteorology and climatology, forestry and agriculture, cartography, creation of geographic information systems, etc.
Naturally, this information should be widely used for the benefit of the oil and gas industry.
One of the most perfect tools for monitoring natural objects is remote sensing. Techniques for non-contact measurements provide extensive operational information about environmental changes. This is especially true for water pollution. Remote sensing methods are dominant in the large-scale comprehensive study of pollution areas in the Caspian Sea. In order to determine the dynamics of pollution of the Caspian Sea, assessment of the situation parameters based on space images and conducting complex monitoring are urgent issues.

Keywords: monitoring, multispectral, aerospace, ArcGIS, Caspian Sea

I. Introduction

As the first step in solving the problem of pollution of the sea surface with oil products, monitoring of polluted basins is one of the important issues. This requires the joint use of remote sensing methods (RS), aircraft and space systems for observation of water areas, detection of pollution, physical characteristics and control of its distribution in areas. The monitoring system should also provide observation in any weather, should not depend on lighting conditions (cloud cover), determine the volume, type, and location of pollution [1].

Remote Sensing (Earth Remote Sensing) transmitters must work on a real-time scale and distinguish anthropogenic pollution from biogenic substances formed in the sea as a result of the life activity of marine organisms. Modern ERS tools used for detection use a wide range of electromagnetic radiation wavelengths: ultraviolet and visible (0.26-0.8 μm), near (0.9 - 3 μm) and far (7 - 14 μm) infrared, ultra high frequency (1-100 sm) bands. They provide virtually real-time marine observations today.

Already at the present time, with the use of aerospace methods and technologies, it is possible to solve many problems in the interests of the oil and gas industry, first of all, who, how:

- conducting fundamental scientific research processes of the formation of hydrocarbon immigration using aerospace information;

- the study of the geological structure of oil and gas-bearing territories, including the study of lineament network and deep tectonics, annular structures,

- conducting tectonic zoning of these territories on the basis of space data for the informational support of prospecting work for the discovery of new and prospective evaluation of existing oil and gas deposits;

- monitoring of the current condition of oil, gas and product pipelines for the detection of leaks, violations of the technical condition, etc.;

- determination of potentially dangerous sections of pipelines, including assessment of changes in floodplains of rivers, reservoirs and swamps as a result of changes in permafrost and hydrophysical properties of soils,

- assessment of the dynamics of the frozen soil regime and the results of its impact, as well as the identification of the most favorable geoecological conditions for the laying of new pipelines;

- monitoring of dangerous natural and man-made processes during the development and transportation of hydrocarbons, including earthquakes,floods, avalanches, landslides, tsunamis, tropical cyclones, etc. on the basis of aerospace data;

- remote monitoring of the ice situation in arctic regions, in vol including locations of drilling platforms and the Northern Sea Route;

- operational space monitoring of fires in buffer zones of main pipelines and other objects of the oil and gas complex;

- environmental monitoring of places of extraction, transportation, processing and distribution of hydrocarbons on land and at sea to assess the consequences and reduce risks from the activities of enterprises in the oil and gas industry, including: no contamination of soil, vegetation and snow cover with petroleum products within the limits of drilling wells, oil storage facilities and oil pumping stations; marine platforms, places of loading, unloading and movement of ships for the transportation of oil, petroleum products and liquefied gas;

- underground and underwater pipelines; revealing the blooming of lakes as a result of the introduction of mineral and organic suspensions, etc.;

- control of tempos and evaluation of the efficiency of recultivation of lands and polluted territories based on aerospace data.

- carrying out ecological passporting of objects of the oil and gas industry using aerospace information;

- determination of the location of pipelines, structures and other objects of the oil and gas industry and formation of their cadastres based on aerospace data;

- creation of digital maps, three-dimensional terrain models, geoinformation systems (GIS) of different thematic orientation for oil and gas districts and others. with the use of aerospace information;

- remote monitoring of unsanctioned cuts into main oil and product pipelines;

- detection of unauthorized economic and construction activities, as well as the appearance of man-made objects in the zones of withdrawal of objects of the oil and gas complex based on aerospace data;

- remote monitoring of districts of construction of new facilities of the oil and gas complex;

- monitoring from space of places of combustion of accompanying gas and control of the functioning of torch installations;

- informational provision of long-term planning and management of the activities of these enterprises and the liquidation of accidents on them using aerospace data and others.

The spectrum of these tasks can be expanded as the methods, technologies and technical means of remote sensing and processing of the received information are developed.

II. Research object and methodology

Geographical Information Systems (GIS) are widely used today to determine water quality models and parameters. As we know, ArcGIS software is one of the integrated programs included in the GIS system. In this article, ArcGIS 10.4.1. the version of the software was used, the parameters causing oil pollution in a certain area of the Caspian Sea and the assessment of the degree of pollution were analyzed.

In order to determine the sources of pollution of the Caspian Sea in the Neftchala area, the space image of the AZERSKY satellite provided by Azercosmos was used. Satellite resolution 1.5m panchromatic / 6m multispectral; color range: 4 bands (red, blue, green, near infrared); shooting scene: min. 60X60km, max. 60X600km; height: 694.9 km; ability to draw the same point: 2 days (45°) .

Due to the fact that the Caspian Sea is a unique lake, it is very important today to evaluate its characteristics and ecological condition, as well as to study its hydrometeorological, hydrogeological and hydrophysical characteristics, and to analyze the variability of hydrochemical and hydrobiological processes. Among the problems of the Caspian Sea, along with the fluctuation of the level, the pollution of the sea waters and the related deterioration of the environmental conditions are the most important problems of the last period. The main sources of pollution of the Caspian Sea are the rich natural resources of its basin and the sewage flows of cities and industrial facilities located on the coasts of its basin, oil tankers, offshore oil fields, oil refineries, ship and boat lubricants, oil pipelines, oil wells, accidents, as well as the negligence of service personnel. The dynamics of the ecological situation of the Caspian Sea and, at the same time, its pollution by oil products occupy a key place in the ecological assessment. The first step is to identify the sources that pollute the sea as a result of natural and anthropogenic influences. A deeper study of the interaction of hydrophysical processes occurring in the water basin is important in order to reveal the regularity of the characteristics of the distribution of pollutants throughout the water area. On the other hand, the study of these factors separately and at the same time reveals that they play a more influential role and shows the main reasons for such a distribution [1,4].

III. Analysis of results

The spatial image includes the combination of the image of the Neftchala area in 2020 in panchromatic and multispectral bands (Figure 1). The description opens in the ArcMap version 10.4.1 interface of the ArcGis software. ArcMap has high-quality cartographic production functions that enable graphical and verbal data display, data registration, query and analysis, and development of images and reports. "Add Data" command is used to open the spatial image in ArcMap.

In order to facilitate the processing of the space image, a range shift was performed between the bands of the (Mosaic_2020) image presented to us.

With this, it is more convenient to work on the objects we need in the image. It should be noted that the color range of the image consists of 4 bands (Blue Band_3, Green Band_2, Red Band_1, Infrared Band_4). As seen in the mosaic image, Red Band_1 to Red Band_4, Green Band_2 to Green Band_1, Blue Band_3 to Blue Band_2, and Infrared Band_4 to Infrared Band_3.

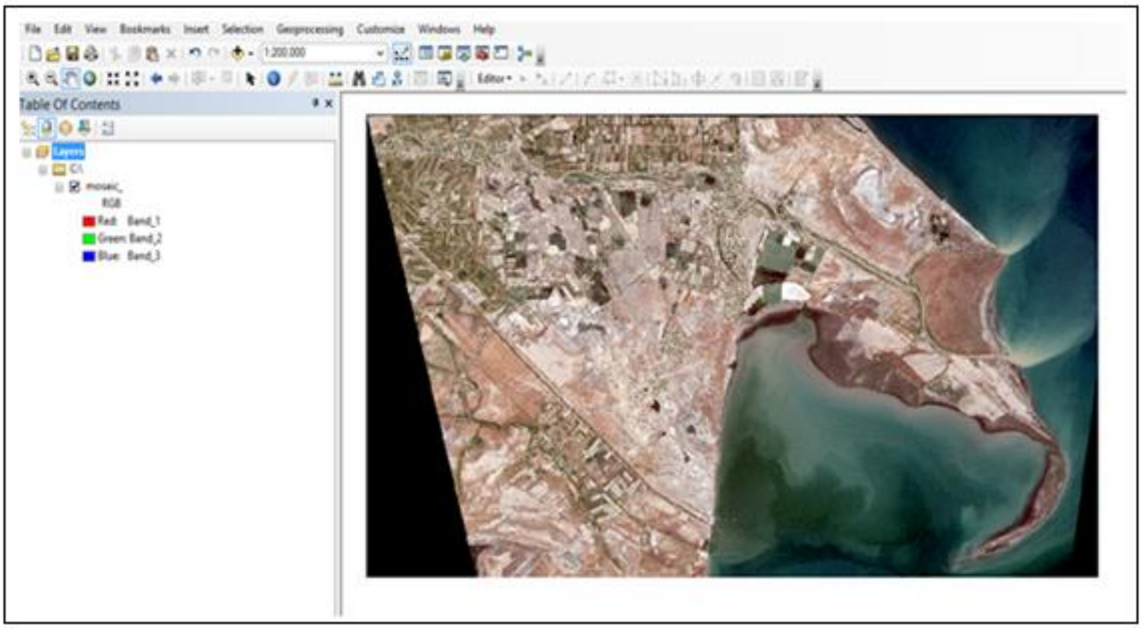

Figure 1: *Space image of Neftchala area in panchromatic and multispectral bands*

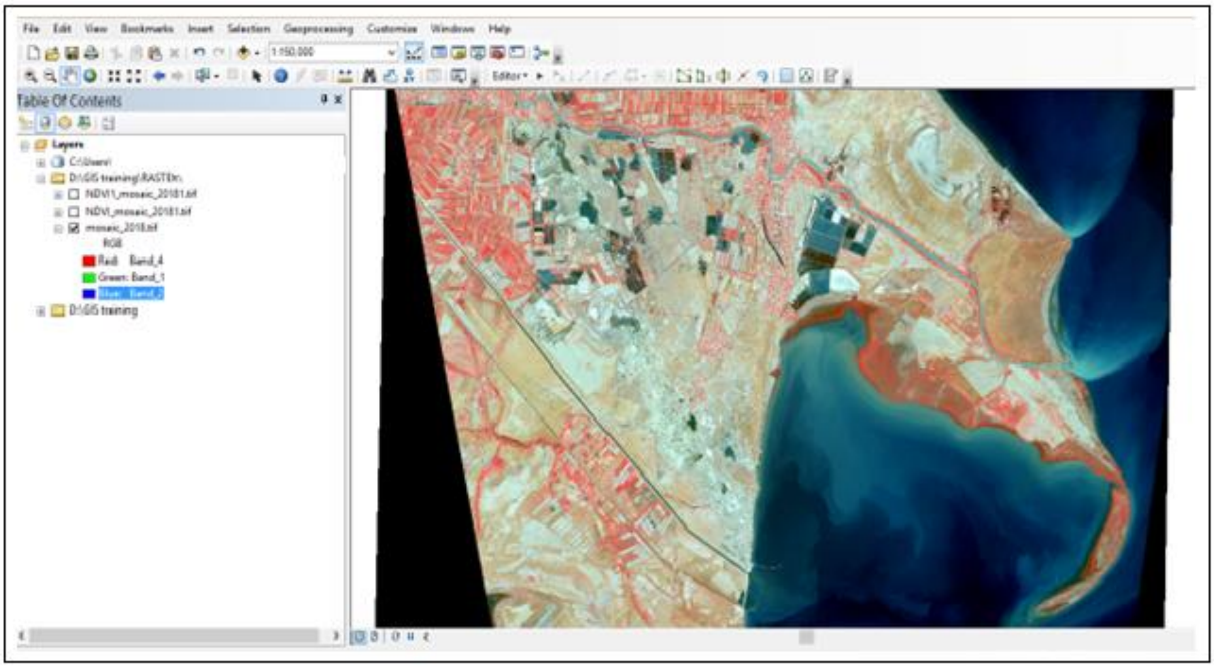

Figure 2: *Bandwidth-shifted space image*

After changing the color ranges, we get a chance to more clearly select water bodies in the image, and the "Start Editing" command is selected from the "Editor" button on the ArcMap toolbar, and mapping work is carried out on the image (Fig. 3).

Hasanabad and Gobu canals have been designated in the description and processing works have been carried out on them (Figure 3). It should be noted that the Hasanabad collector starts from Boyat village of the region, passes through the territory of "Anshad-Petrol" MM, collects groundwater in the flow direction and flows into the Caspian Sea. Where the stream empties into the sea, the coastline is semi-swamped.

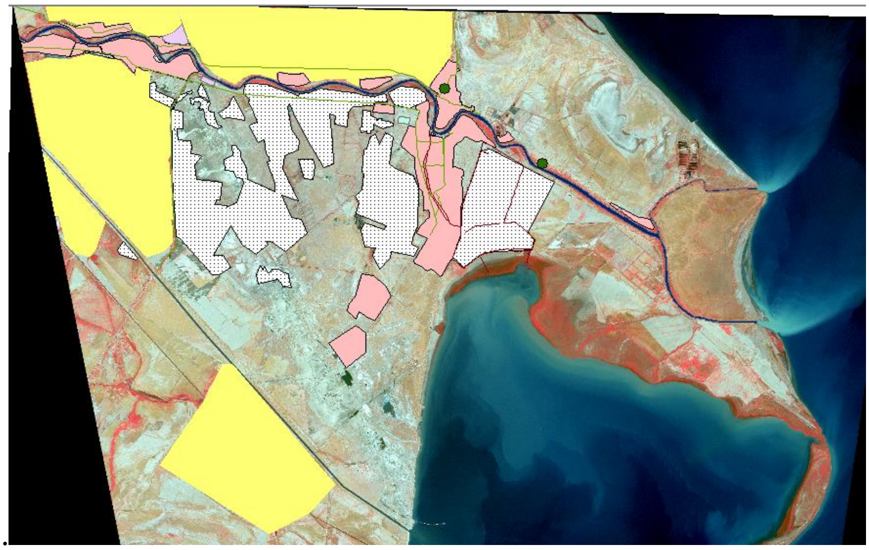

Figure 3: *ArcGis 10.4.1 in Neftchala area. conducting vectorization work through software*

Mapping works are carried out mainly in the coastal part of the Neftchala area close to the Caspian Sea, as well as on runoff waters discharged into the Caspian Sea, fishing facilities, unused land and other objects. Neftchala region is from Salyan to the north, Masalli, Lankeran to the south. It borders Bilasuvar and Jalilabad from the west, and the Caspian Sea from the east for 123-130 km.

Figure 4: *Classification assessment of the Caspian Sea with NDWI*

In NDWI, a combination of green (Band_2) and near-infrared (Band_4) bands was used as a range for defining and delimiting the open water surface (1). The NDWI (Normalized Water Index Difference) index is expressed as follows.

$$NDVI = \frac{GREEN}{GREEN+NİR} \qquad (1)$$

Here, NDWI - Normalized Water Index Difference
GREEN - Green range
NIR - Near Infrared range.

In our research, using the NDWI index, we were able to clearly determine the level of pollution of the Caspian Sea in our aerospace image. For more accurate monitoring, 5 values are included in the classification of the image (Fig. 4).

As can be seen from Fig. 5, the degree of water transparency increases from orange to blue. The white color represents dry land.

We clearly see that the Hasanabad channel in the Neftchala area coincides with the ground data mentioned above as a result of the email, and that it pollutes the Caspian Sea. The water discharged from the canal is represented by the orange color of the NDWI index according to the level of pollution.

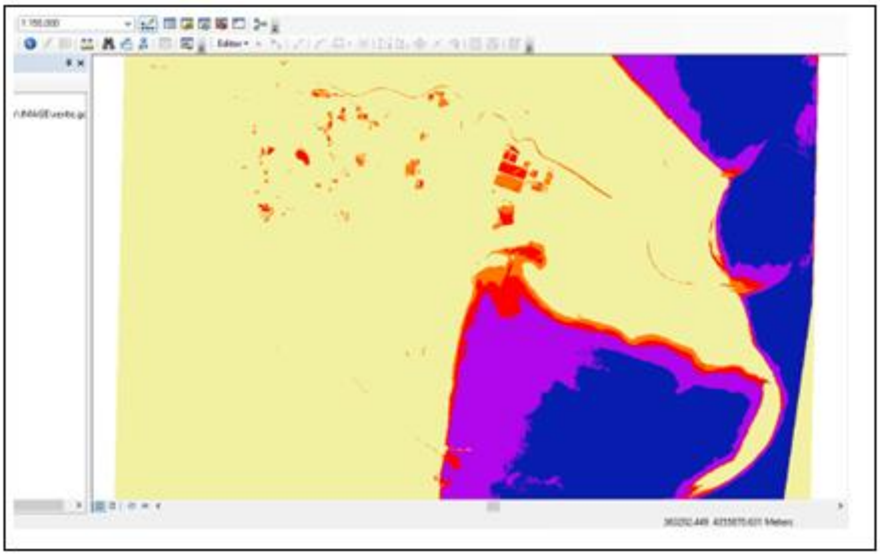

Figure 5: *ArcGis 10.4.1 of the Caspian Sea in Neftchala area. contamination rate estimation through software*

The cartographic basis for the oil pollution distribution map is the GIS-Caspian Ecological program overlay, which contains the following data: the coastline of the Caspian Sea, the hydrographic network (rivers and lakes), settlements, locations of oil fields on the shelf and on the coast, important oil pipelines of the region, the integrated scheme of the flow, digital model of underwater topography.

After preparing the cartographic base, an information layer containing data on the distribution of oil and oil products cover was added to the map. Then the layers are automatically combined and the final shape of the map is made.

The obtained map of the distribution of oil and oil products cover in the water area of the Caspian Sea characterizes its situation (real scale 1:1 500 000). The general pattern of distribution and transport of oil and oil products cover is related to the active exploitation of oil fields on the shelf and on the coast and is consistent with the global flow system of the Caspian Sea.

As can be seen from the map, the water area of the Caspian Sea is highly polluted by oil products. Due to the modern development trend of oil fields in the Caspian Sea, it can be concluded that if appropriate measures are not taken, the scale of pollution will increase. In this regard, the need to create an international oil pollution monitoring system based on a periodically updated map of their distribution, integrated with the geodatabase [2-4] is obvious.

In order to solve the issue of efficient use of resources, it is important to take an ecological-economic approach, and even to protect the environment and bioresources together with industrial activity in the shelf area. The main indicator of the level of change in the ecological situation is the concentration of pollutants and the distribution of areas in the water area. The analysis and evaluation of the indicators of oil products in the area of the Caspian Sea belonging to the Republic of Azerbaijan and the construction of maps based on the data collected in recent times have been of great importance in solving environmental issues.

As can be seen from Fig. 7, high-volume oil pollution (0.20-0.15 mg/l) in the Baku Bay area is characterized by the next result based on the average annual oil pollution data for 2017-2020. For these years, the average annual distribution of petroleum products areas in the Caspian Sea area was determined by the degree of pollution in those areas (0.09-0.06 mg/l). Analyzing the dynamics of the ecological situation based on the average annual calculations of these indicators and the constructed maps is very useful for predicting the ecological situation in the future from a scientific theoretical point of view.

Figure 6: *Average annual distribution of oil products to fields for 2017-2020*

Crude oil spills on land and seas have created the need to develop environmentally friendly and efficient methods for cleaning up these pollutions. Petroleum hydrocarbons, which cover large areas of the water surface with the thinnest layer, reduce the amount of dissolved oxygen by reducing gas exchange. A surface layer that reduces water evaporation leads to a violation of heat transfer. A further decrease in the amount of dissolved oxygen is associated with the biodegradation of hydrocarbons by microorganisms. As a result of these processes, decomposition products that are toxic to living organisms also accumulate in water. In addition, in the presence of oil hydrocarbons, the toxicity of other pollutants, especially metals and chlorinated hydrocarbons, becomes more pronounced. Due to the negative effects on living organisms in the environment, it is necessary to eliminate the consequences of oil spills. As can be seen from the literature [5-7], in modern times, various reagents and there are many methods of cleaning oil-contaminated objects using adsorbents.

IV. Conclusion

Based on the NDVI and NDWI indices, the pollution dynamics of the coast line of the Caspian sector of the Caspian Sea were investigated, the values of these indices were calculated, the pollution zones corresponding to certain intervals were determined and the corresponding areas were calculated. It has been shown that using GIS technologies and remote sensing data, it is possible to calculate the change and pollution of the coastal zone of the

Azerbaijani sector of the Caspian Sea based on the values of NDVI and NDWI indices. The proposed methodology allows to easily calculate what part of the total area the research area is. The obtained results can be used in the assessment of the change trend of the objects and processes that shape the dynamics of the coastline in the following periods and in the preparation of predictive proposals.

Abstract

Based on the data from the catalog we compiled about natural disasters in Georgia, the frequency and probability of max hurricane magnitude in various zones of Georgia for the period 1961-2022 was studied. On the nature of the distribution of wind speed, frequency, intensity and magnitude of hurricanes, 3 zones are distinguished on the territory of Georgia. Zone 1 covers the Main Caucasus Range, the Likhi Range, as well as a small area of the interior of the Colchis Lowland and a small area of the flat part of Kvemo Kartli. Zone 2 covers the intermountain depression of Georgia - the Black Sea coast, the Colchis lowland, the Imereti Upland, the plains and foothills of eastern Georgia, with the exception of a small territory of the interior of the Colchis lowland and a small territory of the flat part of Kvemo Kartli, which are included in zone 1. Zone 3 covers the western part of Meskheti ridge, a significant part of the Trialeti ridge and the Akhalkalaki plateau. In particular, the following results were obtained. The most active hurricane zone is zone 1 (the frequency of hurricanes is 15 per year and the repeatability *period is 0.09 years, ≈ 1 month). The least active hurricane zone is zone 3 (1-2 hurricanes occur per year,* repeatability *period is 0.9 years, ≈ 10-11 months). The highest frequency of hurricane magnitudes by zone is as follows: zone 1 - 3.6÷4.0 (87%), zone 2 - 3.1÷3.5 (44%), zone 3 - 3.6÷4.0 (more than 60%). In the first two zones, as magnitudes increase, their frequency decreases significantly. The probability curves for the max magnitude of hurricanes are well approximated by polynomials of the 5th degree. The expected hurricane magnitudes in these zones are: in zone 1 - 5.8, in zone 2 - 5.5 and in zone 3 - 4.5 with a probability of 0.2%, 0.5% and 1%. The repeatability periods of such magnitudes are 500 years, 200 years and 100 years, respectively. Thus, in the coming decades, it is most likely that the magnitude of hurricanes in zone 3 will increase to 4.5; some increase in the magnitude of hurricanes to 5.5 in the long term is possible in zone 2, and in zone 1, hurricanes will intensify to magnitude 6 is unlikely. A map of zoning the territory of Georgia according to the max possible hurricane magnitudes has been developed. There are two areas with the highest max magnitude, reaching 6 (the Southern part of the Likhi Range in Western Georgia and a small area of the flat part of Kvemo Kartli in Eastern Georgia). Hurricanes with magnitudes 5 and 5.5 are possible in some areas. In a significant part of Georgia, the max hurricane magnitude can reach 4.5.*

Keywords: hurricane, provision, frequency, period, magnitude

I. Introduction

The strongest gusts of wind recorded on Earth are associated with tornadoes and reach speeds of up to 500 km/h. If a tornado of such force passes through a populated area, there will be practically nothing left of it [https://www.meteovesti.ru/news/63388088280-kakovo-maksimalnoe-znachenie-skorosti-vetra-zafiksirovannoe-na-zemle]. An automatic weather station on the Australian island of Barrow during Cyclone Olivia on April 10, 1996 recorded a gust speed of 113 m/s (408 km/h) [https://en.wikipedia.org/wiki/Cyclone_Olivia], and on April 12, 1934 at the Mount Washington Observatory in New Hampshire the speed the wind gust was 103 m/s (371 km/h) [1]. Winds of 333 km/h (about 87 m/s) were recorded at the US air force base in Greenland and Adélie Land in Antarctica (https://ru.wikipedia.org/wiki/%D0%92%D0%B5%D1%82%D0%B5%D1%) [80].

Along the entire Gulf Coast, wind speed reaches 157 knots (more than 80 m/s), (1 knot = 0.514 m/s). The highest wind speeds are along the Gulf Coast from Texas to Alabama. Using the Bayesian approach, the maximum possible coastal wind speed here can be 208 knots (more than 106 m/s) [2].

A study of high winds in Florida found that the city of Miami can expect hurricane-force winds of 50 m/s (45.5–54.5 m/s - 90% confidence interval) or stronger to occur on average once every 12 years, and in the city of Pensacola hurricane winds of 50 m/s (46.9–53.1 m/s, 90%) or stronger can be expected to occur every 24 years [3].

The Monte Carlo simulation method was used to estimate hurricane wind speeds along the Persian Gulf and the east coast of the United States. Estimated calculations of hurricane wind speeds were made at a height of 10 m above the ground in open areas near the coastline and at a distance of 200 km inland. Estimated hurricane wind speeds were found to best fit Weibull distributions [4].

Maximum hurricane wind speeds in China show a decreasing trend over large areas. Only in the southeast of the Tibetan Plateau does the wind speed not significantly decrease, but, on the contrary, even increase [5,6].

A weakening of hurricane winds was also noted in North America [7,8], regions of Europe [9,10], Australia [11], etc. Tendencies of increasing strong and stormy winds over the world's oceans were noted [12]. According to passive microwave satellite data [13], wind speed in the tropics for the period 1987–2006 increased on average by 0.6% per decade, while for all oceans the average trend was 1.0% per decade.

Hurricanes pose a danger to Georgia. Research on hurricane winds in Georgia has a long history, although the most relevant work has been carried out in recent years. In the article [14] for the period 1961-2008, the statistical structure of hurricane winds was studied, the number of days and duration of hurricane winds were determined, the empirical functions of their distribution and the size of their areas were studied. The monograph [15] examined the geography, structure, areas and dynamics of hurricane winds, and in article [16] the spatial distribution of hurricane winds was assessed, the maximum economic losses were calculated, and a map of expected risks was constructed. The paper [17] presents preliminary studies of hurricanes winds in Georgia in the period 1961-2022. Over the entire study period, about 1600 cases of hurricane winds were recorded. During the year, hurricanes occur on average 20 times, with the highest number of cases recorded in 2002 – 81. The average speed of hurricane winds in general for Georgia is 36 m/s, the highest speed reached 56 m/s. The average hurricane area is about 1200 sq. km, and the maximum hurricane area exceeds 10000 sq. km. There is no clear relationship between the hurricane area and the corresponding material damage, which can most likely be explained by the heterogeneity of the level of urbanization of comparable areas that experience varying degrees of damage. The long-term changes in hurricane activity reveal a cyclical nature, which can be explained by the peculiarities of atmospheric circulation. In general, over the entire period there has been a tendency for hurricane activity to weaken.

This article is a logical continuation of these studies [14-17]. It uses observational materials for the period 1961-2022 to assess the long-term risk of dangerous hurricanes in Georgia [18].

II. Methods

The article uses materials from the catalog about natural disasters in Georgia [18]. These data comply with World Meteorological Organization standards. All measurements of wind speed were carried out at a height of 10 m above the ground surface. In the catalog, the strength of a hurricane is expressed through magnitude (M), which was defined as a value proportional to wind speed, the proportionality coefficient is conventionally taken to be 0.1 s/m.

Statistical methods for processing climatological data were used. The assessment of the long-term risk of dangerous hurricanes is carried out on the basis of an empirical probability curve showing the probability or probability of exceeding a given value among the totality of the series. The coordinates of the supply curve were calculated directly from the values of the initial series of observations; for each member of the series, the empirical supply was determined using the Gauss formula:

$$P = m/n \cdot 100\%$$

where m is the number of hurricane events of a given magnitude, n is the total number of hurricane events.

III. Results

Based on the nature of the distribution of wind speed, frequency, intensity and magnitude of hurricanes on the territory of Georgia, 3 zones have been identified [19].

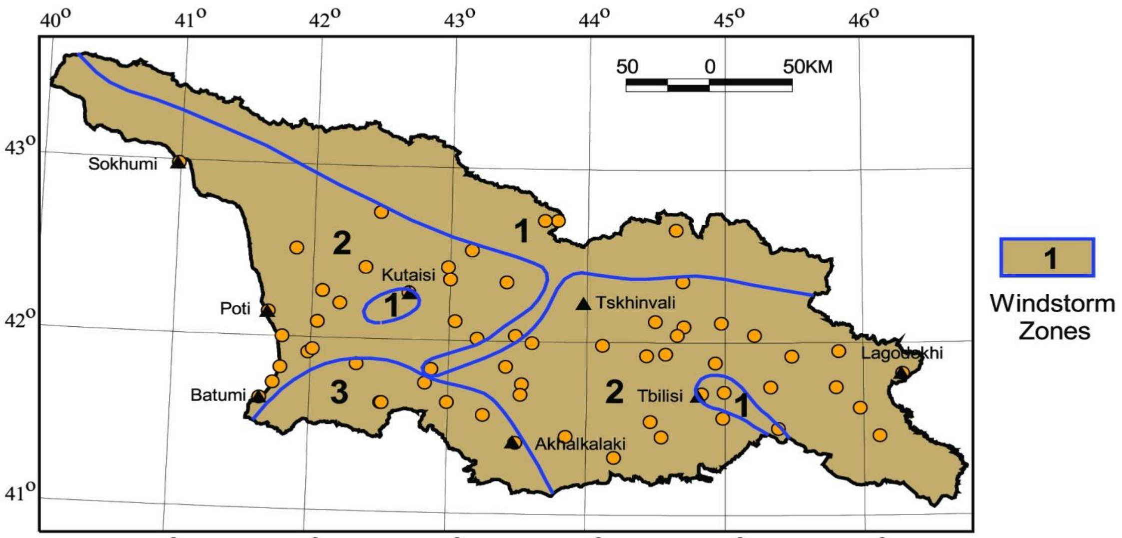

Figure 1: *Zoning of the territory of Georgia according to the nature of the distribution of wind speed, frequency, intensity and magnitude of hurricanes, and the distribution of observation points whose data were used [19].*

Zone 1 covers the Main Caucasus Range, the Likhi Range, as well as a small area of the interior of the Colchis Lowland and a small area of the flat part of Kvemo Kartli. Zone 2 covers the intermountain depression of Georgia - the Black Sea coast, the Colchis lowland, the Imereti Upland, the plains and foothills of Eastern Georgia, with the exception of a small territory of the interior of the Colchis lowland and a small territory of the flat part of Kvemo Kartli, which are included in zone 1. Zone 3 covers the western part of Meskheti ridge, a significant part of the Trialeti ridge and the Akhalkalaki plateau.

From Fig. 1 it follows that the selected zones are not uniformly illuminated by meteorological observations. The densest observation network is in zone 2, which occupies mainly the flat part of the territory of Georgia. In zone 3, on the Main Caucasus Ridge, there is a very sparse observation network.

Table 1 presents information about the meteorological coverage of these zones and the main statistical characteristics of hurricanes in zones of Georgia that differ in the nature of hurricanes. It follows from the table that the most active hurricane zone is zone 1, where the frequency of hurricanes is 15 per year and the repeatability period is 0.09 years (about 1 month). The frequency of hurricanes in zone 2 is 7, and their repeatability period is reduced to 0.14 years (2-3 months). The least active hurricane zone is zone 3, where only 1-2 hurricanes occur per year, and their repeatability period is 0.9 years, i.e. 10-11 months. When converted to one point, the frequency of hurricanes by zones are: 1.7; 0.15 and 0.2; the repeatability period - 0.6, 7 and 5 years, respectively.

Table 1: *Density of the meteorological network and average statistical characteristics of hurricanes in different zones.*

Zone	Number of points (m)	Frequency of hurricanes per year (N)	Repeatability period, T(N) years	Hurricane frequency per 1 point (n= N/ m)	Repeatability period for 1 point on average, T(n) years
1	9	15	0.09	1.7	0.6
2	45	7	0.14	0.15	7
3	6	1.2	0.9	0.2	5

Figure 2 shows histograms of the frequency of occurrence of various hurricane magnitudes. As it follows from this Figure the nature of the distribution of magnitude frequency in different zones is significantly different. In zone 1, in most cases (87%), the smallest magnitudes of 3.6-4.0 characteristic of the zone prevail, and with increasing magnitudes their frequency also decreases. In zone 2, the highest frequency of occurrence of 44% corresponds to gradation 3.1-3.5, and with increasing magnitudes their frequency of occurrence decreases significantly. In zone 3, the predominant frequency of gradation with the highest magnitude values is 3.6-4.0, which exceeds 60%.

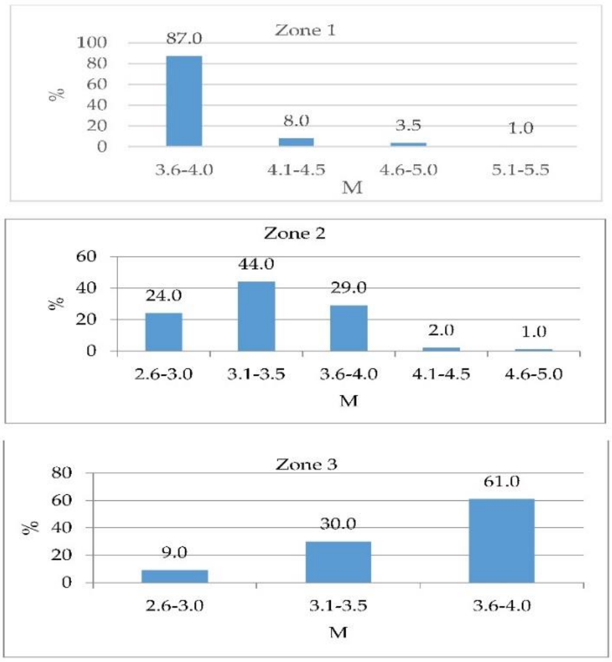

Figure 2: *Repeatability of different gradations of hurricane magnitudes in different zones.*

Figure 3 shows the probability curves for the maximum magnitude of hurricanes in different zones of Georgia, characterized by different wind speed regimes, and with different values of frequency, intensity and magnitude of hurricanes, as well as their approximation by a 5th degree polynomial.

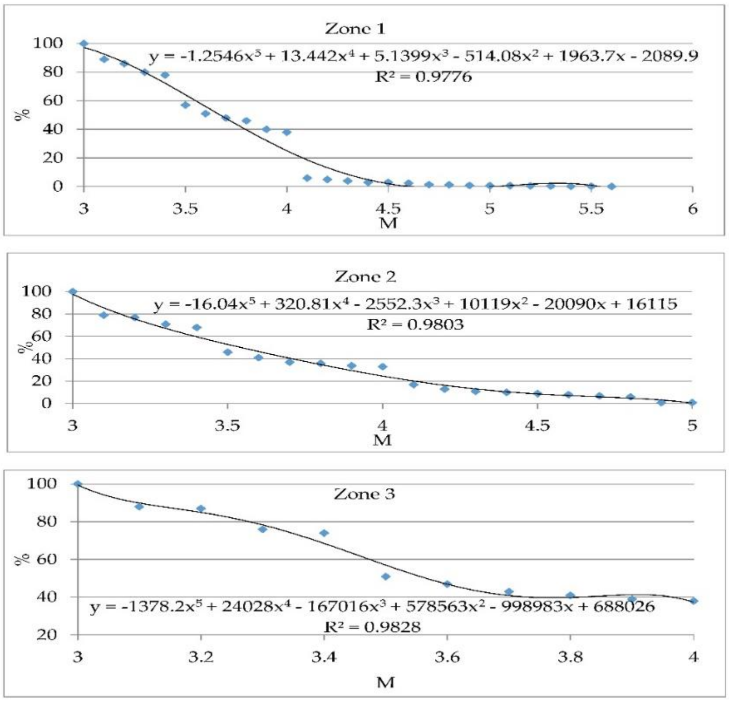

Figure 3: *Curves of provision for the maximum magnitude of hurricanes and their approximation by a 5th degree polynomial for various zones (R^2 - coefficient of determination).*

From Figure 3 it follows that the coordinates of points calculated directly from the values of the initial series of observations are well approximated by polynomials of the 5th degree. The coefficient of determination is significant and exceeds 0.97. Thus, the resulting equations can be used to calculate the magnitude of hurricanes of any provision.

Table 2 presents the observed and expected hurricane magnitudes, according to our expert estimates, and the corresponding probabilities for various zones of Georgia.

Table 2: *Values of observed and expected hurricane magnitudes (M_{max}) and corresponding provision (P%) and repeatability periods.*

Zone	Observed M_{max}	Provision, P%	Repeatability period, years	Possible M_{max}	Provision, P%	Repeatability period, years
1	5.6	0.4	250	5.8	0.2	500
2	5.0	1	100	5.5	0.5	200
3	4.0	38	2.6	4.5	1	100

From Table 2 it follows that in the most hurricane-active zone 1, the magnitude reaches 5.6 with a provision of 0.4%, i.e. the repeatability period is about 250 years. In zone 2, the highest magnitude reached 5.0, the provision of which is only 1%, and the repeatability period is 100 years. The highest hurricane magnitude in zone 3 was recorded as 4.0 with a provision of about 40%. Therefore, the repeatability period for this magnitude is about 2.6 years. According to expert estimates, the expected hurricane magnitudes in these zones are 5.8, 5.5 and 4.5, respectively, with provision of 0.2%, 0.5% and 1%. The repeatability periods of such magnitudes are 500 years, 200 years and 100 years, respectively.

Thus, in the coming decades, it is most likely that the magnitude of hurricanes in zone 3 will increase to 4.5; a slight increase in the magnitude of hurricanes to 5.5 in the long term is possible in zone 2, and in zone 1, an increase in hurricane magnitude to 6 is unlikely.

IV. Discussion

1. Based on the nature of the distribution of wind speed, frequency, intensity and magnitude of hurricanes, 3 zones are distinguished on the territory of Georgia. The most active hurricane zone is zone 1, where the frequency of hurricanes is 15 per year and the return period is 0.09 years (about 1 month). The frequency of hurricanes in zone 2 is 7, and their repeatability period is reduced to 0.14 years (2-3 months). The least active hurricane zone is zone 3, where only 1-2 hurricanes occur per year, and their repeatability period is 0.9 years, i.e. 10-11 months. When converted to one point, the frequency of hurricanes by zone is 1.7; 0.15 and 0.2, and the repeatability period is 0.6, respectively; 7 and 5 years old.

2. The nature of the distribution of magnitude frequency in different zones is significantly different. In zone 1, in most cases (87%), the smallest magnitudes of 3.6-4.0 characteristic of the zone prevail, and with increasing magnitudes their frequency also decreases. In zone 2, the highest frequency of occurrence of 44% corresponds to gradation 3.1-3.5, and with increasing magnitudes their frequency of occurrence decreases significantly. In zone 3, the predominant frequency of gradation with the highest magnitude values is 3.6-4.0, which exceeds 60%.

3. The probability curves for the maximum magnitude of hurricanes are well approximated by polynomials of the 5th degree. The coefficient of determination is significant and exceeds 0.97.

4. In the most hurricane-active zone 1, the magnitude reaches 5.6 with a probability of 0.4%, i.e. The r repeatability period is about 250 years. In zone 2, the highest magnitude reached 5.0, the probability of which is only 1%, and the repeatability period is 100 years. The highest hurricane magnitude in zone 3 was recorded as 4.0 with a probability of about 40%. Therefore, the repeatability period for this magnitude is about 2.6 years.

5. The expected magnitudes of hurricanes in these zones are in zone 1 -5.8, in zone 2 - 5.5 and in zone 3 - 4.5 with a probability of 0.2%, 0.5% and 1%. The repeatability periods of such magnitudes are 500 years, 200 years and 100 years, respectively. Thus, in the coming decades, it is most likely that the magnitude of hurricanes in zone 3 will increase to 4.5; some increase in the magnitude of hurricanes to 5.5 in the long term is possible in zone 2, and in zone 1, hurricanes will intensify to magnitude 6.

V. Conclusion

In the future, an even more detailed study of hurricane winds in Georgia is planned, including studies of tornadoes that have appeared in recent years in the continental part of the country.

Abstract

The use of thermal waters as a source of renewable energy is considered one of the most important issues. Clean energy can improve human health in the long term by minimizing the risk of climate change, while also reducing deaths from air pollution in the short term. The risk of exhausting the oil and gas resources used by the countries of the world for many years is increasing over time. Also, considering that the oil and gas sector is one of the main causes of climate change, it is necessary to move away from this type of fuel. In this case, there is a need to use alternative and renewable energy sources in the world.

Addressing climate change requires a shift away from fuels such as hydrocarbons to renewable energy sources such as solar, wind, hydro and geothermal. Renewable energy sources are carbon-free and produce fewer emissions, making them an important component in reducing greenhouse gas emissions. Overall, the transition to renewable energy sources is critical to addressing climate change and ensuring a sustainable future for the planet. The favorable geographical position and climatic conditions of the Apsheron Peninsula allow the widespread use of ecologically clean alternative (renewable) energy sources. So, in addition to oil and gas deposits, thermal waters (Bilgah, Dubendi-Zira, Buzovna, Gala, Karachukhur, Lokbatan, Mardakan, Nardaran, Pirshagi, Sabunchu, Surakhani, Shikhov, etc.) are widespread here.

The operating reserve of thermal waters with a temperature of 40-90 ^{0}C on the Absheron Peninsula is 20,000 m^3/day. Although the studies conducted in the study areas show that the forecast reserves of thermal waters here are 27125 m^3/day, it is not doubtful that this indicator is many times higher.

The article describes the perspective of using thermal water deposits on the Apsheron peninsula as an alternative energy source. The analysis of funds and printed materials on thermal water deposits of the research area shows that the energy resources collected in this area can be considered as alternative energy and are of great importance for the future economy of the region. Studies show that the water temperature is high in the zones where the tectonic faults spread directly. As mineral water resources from thermal waters, it is also considered useful for the development of balneological, sanatorium-health complexes.

Keywords: climate change, alternative energy source, geological conditions, degree of mineralization, mineral waters

I. İntroduction

Apsheron peninsula, which is the research area, belongs to the southeastern part of the Greater Caucasus in terms of morphostructure. The sediments of the Cretaceous, Paleogene, Neogene and Quaternary periods are involved in the geological structure of Apsheron. The floors of the upper division of the Cretaceous system are involved. The sediments of these floors came to the surface in north-western Apsheron. The Paleogene system is characterized by strata of the Paleocene, Eocene, Oligocene departments. The Paleocene department is characterized by the

Sumgayit formation. This stratum is characterized by lower, middle and upper semi-stratums. The lithological composition consists of clay, marl, and sandstone layers and its thickness is 80-325 meters. The Miocene branch of the Neogene system is characterized by the Upper Maykop formation, Torton, Sarmatian, and Meotis floors. Clay facies prevailed in Upper Maykop. The Pliocene branch of the Neogene system is characterized by the Pont, Productive layer, Agcagil layers [1].

According to the tectonic structure, the Apsheron peninsula is divided into Western, Central anticlines and Eastern Apsheron synclinal areas.

In the research area, winter months are mild, summer months are hot, and autumn and spring months are cool. Atmospheric sediments fall less in these areas, and strong winds prevail. The type of climate belongs to semi-desert, dry, desert climate. Autumn months are warmer than spring. March and the first half of April correspond to winter, the second half of April and May correspond to summer. In these areas, January, the coldest month, has an average monthly temperature of 1.1 ^{0}C, and June, the hottest month, has an average monthly temperature of 27 ^{0}C. The average annual temperature ranges from 14.3 to 14.7 ^{0}C. The absolute minimum air temperature varies from -18 ^{0}C to -21 ^{0}C [2,3].

In the years when the weather is very hot, the highest temperature is 36-39 ^{0}C in the coastal zone of the sea, and 40-43 ^{0}C in the areas far from the sea coast. The minimum value of the average daily absolute air humidity occurs in January, and the highest value occurs in July-August.

The hydrogeological conditions of the Absheron Peninsula are extremely complex. In Western Apsheron, clay sediments of rocks older than the Quaternary period prevailed. Groundwater in these areas is sporadically distributed in Upper Pliocene and Quaternary sediments. The groundwater spread in these sediments is characterized by a high degree of mineralization. These waters are not suitable for drinking or use for economic purposes. Groundwater with sweet and weak mineralization is very rare [4,5].

Pressurized groundwater in pre-Quaternary sediments is commonly associated with oil fields. Most of these waters have a high degree of mineralization. Iodine, bromine, potassium, lithium and other microcomponents are widely distributed in these waters.

Groundwater is almost ubiquitous in Eastern Apsheron. Groundwater in Eastern Apsheron is mainly distributed in Quaternary sediments. The depth of groundwater is from a few cm to 20 m and more. The direction of groundwater flow is from the central parts of the Apsheron peninsula to the shores of the Caspian Sea.

The degree of mineralization and chemical composition of groundwater is very complex. The chemical composition is mainly hydrocarbonate-chlorine. Salty chlorinated waters are widespread mainly in Bina-Hovsan muldas, where oil-waste waters are spread, while in other areas weakly saline and saline waters are widespread. Pressurized waters in Upper Pliocene and Quaternary sediments are fresh and weakly saline. Underground pressurized waters lying in older strata are characterized by high mineralization rates [6,7].

II. Methods

The formation of groundwater in the Apsheron peninsula took place under different conditions. Both natural and man-made factors played a role in the formation of underground water in the Apsheron Peninsula.

Geological-geomorphological conditions are the most important factor in the formation of groundwater on the Apsheron Peninsula. Since clayey rocks of various ages spread in Western Apsheron cover the earth's surface, they did not create conditions for the formation of groundwater in this area. In some areas, as a result of the outcrop of limestone and sandy rocks, it has created conditions for the formation of groundwater here. Geological-geomorphological conditions in Central and Eastern Apsheron are favorable for the formation of groundwater. So, since the lithological composition of these areas includes sand, sandstone, and limestone, groundwater is spread everywhere in these areas. As is known, relief plays a key role in the formation of groundwater. Therefore, in the Apsheron peninsula, groundwater is more common in the low areas of the terrain. Thus, atmospheric sediments, which are already small in these areas, are collected and filtered underground, forming groundwater.

Climatic factors are quantitative and qualitative indicators of groundwater formation. On average, 227 mm of annual precipitation falls in the study area, and evaporation is 947-1344 mm. The total mineralization rate of atmospheric precipitation varies from 56 to 208 mg/l. 184.8 kg/ha of salt fall during the year due to atmospheric precipitation. 12.9% of these salts were NaCl. In addition, water formed from condensation vapors in the air plays an important role in the formation of groundwater.

Artificial factors play an important role in the formation of groundwater on the Apsheron Peninsula. Artificial factors are formed as a result of human activity. These include irrigation of fields, feeding with highly mineralized water extracted from oil wells, losses from the Samur-Apsheron canal, etc. includes. Apart from these, groundwater in the Baku synclinal soil is also fed by losses from water lines. As underground water resources are limited in the Apsheron peninsula, the waters of the Samur-Apsheron canal were widely used for irrigation purposes. Due to the losses from this channel, fresh groundwater is found in areas along the channel suitable for the formation of groundwater. According to calculations, the annual loss from this channel is 5-10%.

The process of formation of hydrogeological conditions on the Apsheron Peninsula is extremely complex. Geomorphological, tectonic, geological-lithological conditions, the activity of the Caspian Sea, and climate indicators are involved to some extent in the process of underground water formation. It is impossible to reconcile with the classifications determined in the process of formation of hydrogeological conditions in Apsheron territory and accepted for general geological structures. Distribution of geological stratigraphic divisions on the Apsheron peninsula, their lithological compositions are heterogeneous on the area, and the geomorphological-tectonic structures of the areas confirm the so-called.

Common patterns for the studied areas include uneven distribution of surface water, lack of rivers, low atmospheric precipitation, and several times more evaporation than atmospheric precipitation.

In the territory of the Apsheron peninsula, clayey facies are abundant in stratigraphic units of different ages. The collector layers involved in the cutting are in the form of laminations, the aquifer rocks contain clay, the layers separating them consist of solid, thick-layered clays, the presence of various salts in the clay rocks, etc. created conditions for the formation of fresh and slightly saline water horizons in these areas. Complex tectonic conditions in the researched areas also confirm what we said. Thus, the alternating anticlines and synclines consisting of rocks of different ages in the area, the presence of numerous tectonic fractures and disturbances have led to the formation of water complexes that are completely unrelated to each other [8,9].

The natural state of hydrogeological conditions in Apsheron Peninsula is uncertain in different areas. So, with the exception of some areas of Western Apsheron, fundamental changes have occurred as a result of human anthropogenic activity in most areas. For many years, in some areas of the Apsheron Peninsula, the groundwater levels have approached the ground surface, their distribution areas have increased, and the process of sweetening of groundwater has begun. In some areas, the opposite was observed. All this had a certain effect on the formation and change of the hydrodynamic and hydrochemical conditions of the areas [11,12].

Apsheron Peninsula is one of the most widespread areas of thermal and mineral waters in the Republic of Azerbaijan (Fig. 1). The operating reserve of thermal waters with a temperature of 40-90 ^{0}C on the Apsheron Peninsula is 20,000 m^3/day.

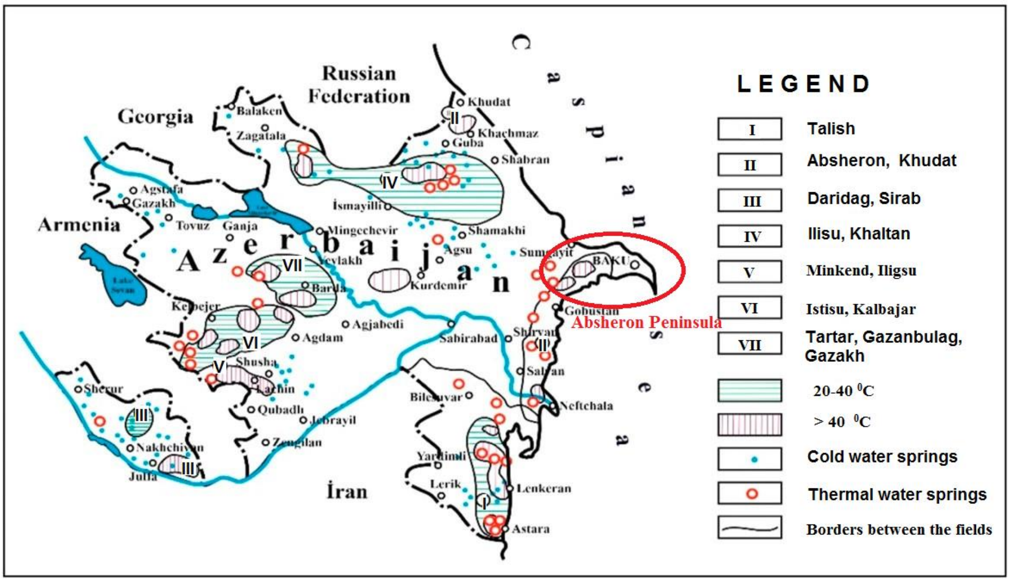

Figure 1: *Mineral-thermal waters map of Azerbaijan*

Formation water temperature. When determining the temperature of the layers, the terms geothermal step and geothermal gradient are used. The temperature of formation water inside the hydrocarbon deposits is taken according to the geothermal gradient of the formation. Taking this into account, it is possible to calculate the temperature of the water inside the layer using the following formula:

$$T = a + H/k$$

T – formation water temperature, °C;
a – average annual temperature on the earth's surface;
H – the depth where the layer is located, m;
k – geothermal gradient, m/°C.

The temperature of the layers was measured for the first time in 1880 on the Apsheron Peninsula (Sabunchu) at a depth of 100-200 m. Later Sh.F. Mehdiyev for the first time determined the geothermal stage by conducting large-scale research works in the Balakhani-Sabunchu-Ramana oil fields. As a result of these studies, it was determined that the geothermal step in shallow oil fields of Apsheron region varies between 21-37 m [11]. Temperatures can reach higher levels in layers in deep deposits. Table 1 provides information on temperature indicators of different depths in the structures of the Apsheron Peninsula.

Table 1: *Temperature indicators of different depths in the structures of the Apsheron Peninsula*

Temperature indicators	Depth, m								
	1000	1500	2000	2500	3000	3500	4000	4500	5000
Average temperature of rocks, ^0C	43	52	60	70	78	86	97	105	112
Geothermal step, m/^0C	33,6	38,8	42,9	44,1	46,4	48,2	48,4	49,1	50,7
Geothermal gradient, ^0C/100 m	2,97	2,57	2,32	2,26	2,15	2,07	2,06	2,03	1,96

The Apsheron Peninsula has a large number of thermal water resources. Thus, among the largest thermal water deposits, Dubendi-Zire, Surakhani, Baku Muldasi, etc. can be shown. Although the studies conducted in the study areas show that the forecast reserves of thermal waters here are 27125 m^3/day, it is not doubtful that this indicator is many times higher (Table 2).

Table 2: *Forecast reserves of thermal waters of Apsheron Peninsula*

Thermal water deposits	Forecasting reserve, m^3/day
Buzovna	4
Gala	1006
Surakhani	2811
Baku Muldasi	3087
Bine-Govsan	1270
Dubandi-Zire	18947
Total	27125

Jurassic and Cretaceous sands and sandstones, flysch clay shales, Paleogene and Neogene clay rocks are mainly involved in the geological structure of the areas where thermal and mineral water deposits are spread.

Mineral-thermal water deposits of Apsheron are concentrated in different stratigraphic horizons. It should be noted that the formation of mineral thermal waters of the Absheron Peninsula is also greatly influenced by mud volcanoes and various types of reservoir waters of oil fields. About 80% of the 20 deposits registered here are hydrogen-sulfide (H_2S), and about 20% are methane (CH_4)-containing gases.

While chlorinated-sodium waters with a high content of calcium and magnesium form a specific group on the Apsheron Peninsula (Surakhani, Amirjan, etc.), mineral waters in the Shikhov region, located in the southwest of Baku, are characterized by a chlorinated-hydrocarbonate-sodium type composition.

The Apsheron peninsula is rich in mineral and thermal waters, important for treatment. Hydrogen sulphide mineral water wells and sources are located near Surakhani, Amirjan, Gala, Binagadi settlements, in Pirallahi, and therapeutic mud volcanoes - Lake Boyukshor, Masazir, Murdalabi, Fatmayi, Ramana, etc. spread in the areas. Here, three processes – oiliness, mud volcanism and mineral water formation processes occur in interaction.

Mineral-thermal waters of the Apsheron Peninsula are found in different stratigraphic horizons - in the sediments of the Pont floor characterized by sand and limestone-sandstone intermediate clays, in the sandstone sediments of the productive layer with a large thickness. Hydro-geothermal indicators calculated for different depths of the aquifer complex of the Absheron Peninsula are given in Table 3.

As a result of the conducted research, the highest temperature of thermal water in the Apsheron peninsula was recorded in Duvanni area (76 ^{0}C), Surakhani area (52 ^{0}C), and Kenizdag area (56 ^{0}C) (Table 4). There is no doubt that the temperature is even higher as you go deeper.

III. Results

It is of great importance to comprehensively study underground thermal water, which is an ecologically clean source of energy, along with other types of fuel (mainly oil, gas) and provide it to the people.

The formation of hydro-geothermal conditions on the Apsheron peninsula reflects the geological-lithological, geomorphological, tectonic conditions of the area. The formation of hydrochemical conditions was influenced by waste water from oil fields and various household wastes. Along with these factors, the rocks of the aeration zone are also important in the formation of the chemical composition.

On the Apsheron peninsula, thermal and mineral waters are distributed in Khazar-Khvalin, Baku, Apsheron, and Productive layer sediments. There is a little hydraulic connection in the sediments of the Caspian-Khvalin. The pressurized waters lying in the Baku-Productive layer sediments have no hydraulic connection. Hydrochemical conditions were formed separately.

Table 4: *Hydro-geothermal properties of thermal waters on the Apsheron Peninsula*

The operating reserve of thermal waters with a temperature of 40-90 ⁰C on the Apsheron Peninsula is 20,000 m^3/day. Although the studies conducted in the study areas show that the forecast reserves of thermal waters here are 27125 m^3/day, it is not doubtful that this indicator is many times higher.

The thermal and mineral waters of the Apsheron Peninsula contain various gases that have a positive effect on the human body, specific chemical components and pharmacological ingredients, and useful biologically active elements, so they can be used for the treatment of many diseases. Although mineral-thermal water deposits containing iodine, bromine and other chemicals with great healing power are currently not used enough, their widespread use in the field of balneology and spa treatment in the near future is currently considered promising and necessary.

Abstract

The paper discusses issues related to global climate change. It's identified that climate change is associated with global warming, caused by a sharp increase in the concentration of greenhouse gases in the atmosphere. Climate warming is accompanied by intense snowmelt and water evaporation. The cloud cover that accumulates in the atmosphere contains a tremendous amount of water, which falls as prolonged heavy rainfall, leading to catastrophic floods accompanied by mudflows, landslides, and erosion processes. The authors developed simple, reliable, and relatively inexpensive protective structures used during floods, mudflows, and landslides. Additionally, new designs for coastal protection were developed. The construction of these structures utilizes waste materials such as recycled tires and reinforced concrete sleepers.

Keywords: engineering-ecological, method, protection, disaster, global, climate, atmosphere, water, waste, warming, coastal protection, flood, mudflow

I. Introduction

Global climate change has become a major scientific and political issue only in recent decades. Politicians around the world often avoid analyzing survey results that indicate growing public concern. Scientific journals are overloaded with publications on this topic, analyses, and commentaries.

In May 1990, climatologists from around the world, in a report for the Intergovernmental Panel on Climate Change (IPCC) established in 1988 by the UN General Assembly to draw the attention of world leaders to the serious problems of global climate change, stated it very clearly. "We are confident," said more than 300 scientists from over twenty countries, "that emissions into the atmosphere caused by human activity are leading to a significant increase in the concentration of greenhouse gases in the atmosphere. This increase in carbon dioxide concentration enhances the greenhouse effect, resulting in additional warming of the Earth's surface.

Even 25 years ago, scientists had predicted, based on climate computer models, an average temperature increase of about 1°C over thirty years if the rate of greenhouse gas emissions in the atmosphere remained at the levels existing at the end of the last century. An increase of one degree may not seem significant, but this is an average across the entire globe, where temperatures have never risen this quickly based on paleoclimatic data. In less than half a century—if current trends continue - we will face temperatures unprecedented since humanity has existed on the planet.

At that time, the scientists and IPCC experts stated that their estimates were likely to be somewhat understated: the number of uncertainties inevitably present in climate change calculations is immense; and warming is likely to be exacerbated by a series of natural processes.

If the current trend continues, by 2030-2050, the atmosphere will contain a quantity of greenhouse gases that will have a heat-absorbing capacity twice that of the carbon dioxide present in the atmosphere in the mid-twentieth century.

It should be expected that global warming will continue indefinitely unless actively mitigated by the efforts of the human community.

No one can predict with certainty what changes will occur in ocean currents or how the climate will change in any specific location on Earth with the disappearance of Arctic ice.

II. Main Causes and Forecast of Further Climate Warming on the Planet

The reasons for the accumulation of greenhouse gases are not as well defined as is often claimed. The primary cause is industry, which relies on fossil fuels as an energy source. Deforestation is also responsible, as it can lead to a significant increase in carbon dioxide concentration in the atmosphere if remaining forests are systematically destroyed. Additionally, there has been a sharp increase in forest fires, often caused by criminal elements for personal profit. A third source of carbon dioxide in the atmosphere is the decomposition of organic matter in the soil due to warming.

Warming on Earth will occur through physical, chemical, and biological processes at both local and global scales. The central question is whether the quantitative effects of these changes will lead to rapid or slow warming. Negative feedback will reduce the rate of warming if it starts to occur more intensely, while positive feedback will amplify it. Such feedbacks can involve changes in cloud cover or snow cover, as they affect the Earth's surface albedo and, consequently, the amount of energy absorbed. An increase in snow or cloud cover will raise the albedo, reduce the amount of solar energy retained, and decrease the warming process, creating negative feedback. A decrease in the Earth's surface albedo works in the opposite direction, creating positive feedback. These changes were taken into account by climatologists when they conducted quantitative assessments of warming.

Cities, hydroelectric stations, irrigation systems, navigation, changes in waterways, transport, marine life, fishing, and oceanic and coastal water circulation all depend on the freshwater flows that are formed.

Forecasts of changes in surface runoff are unreliable, as are other potential consequences of warming on Earth. Within a narrow range of 1°C to 2°C of overall warming, the general picture seems clear. Beyond this range, the consequences of warming become uncertain. Meanwhile, long-term costly projects require further forecasting of precipitation, the results of which become dubious.

According to forecasts from the second working group of the IPCC, large-scale flooding may occur, for example, in many rivers of Western Europe and the northern rivers of Russia.

IPCC specialists, based on climate models, concluded that if measures are not taken to halt greenhouse gas emissions, sea levels could rise by 10-30 cm by 2030 and by 30-100 cm by the end of the current century. This increase will result from the expansion of seawater due to warming and the melting of glaciers. It is assumed that the effects of melting Greenland and Antarctic ice sheets will be minimal during this century. Other scientists believe that the melting of Antarctic ice will lead to a sea-level rise of more than 5 meters. These analyses are only hypothetical, and local effects may be more significant depending on whether the continental plates in a given area are rising or sinking.

III. Intensification of Catastrophic Processes Due to Global Climate Warming

Since the late 20th century, the frequency of floods has increased, as have the damages caused by them. Currently, the area prone to flooding exceeds 3 million km^2, home to 1 billion people.

Thousands die from floods each year, with annual losses amounting to tens of billions of US dollars. Floods lead to diseases, famine, and numerous ecological problems.

Global climate warming is accompanied by intense snowmelt and water evaporation. The accumulated cloud cover in the atmosphere contains vast amounts of water, which falls as prolonged heavy rainfall, creating catastrophic floods along with mudflows, landslides, and erosion processes.

Due to sharp warming, glacial mudflows caused by intensified glacier melting have become more frequent. These glacial mudflows result from the bursting of subglacial lakes and reservoirs, and they almost always have catastrophic consequences

There is a need to develop economically and ecologically efficient engineering measures to prevent or at least significantly reduce the damage from the increasing catastrophic events caused by global climate changes.

The intensity of glacier melting in mountainous regions, driven by global warming, has led to the emergence of numerous glacial lakes. Recent studies have identified over 2,300 glacial lakes in Nepal and Bhutan, of which 20 have been classified as high-risk for bursting [1].

Global warming has sharply increased the incidence of major floods, inundations, and mudflow processes. These processes intensify erosion, the destruction of riverbanks, lakes, and seas, as well as landslide phenomena.

The aforementioned issues highlight the need for effective engineering methods for flood protection, bank erosion control, mudflows, landslides, and other catastrophic and emergency events. There is significant interest in using recycled waste materials in the construction of protective structures.

IV. On the Use of Recycled Tires in the Construction of Protective Structures Against Catastrophic Natural Phenomena

The most common type of consumer waste is recycled automobile and tractor tires. Globally, half of all synthetic and natural rubber produced (over 15 million tons annually) is used for tire manufacturing, and ultimately all produced tires become waste after a certain period. The lifespan of automobile and tractor tires is shorter than that of most rubber products [2].

The authors have developed simple and relatively inexpensive protective structures using recycled steel-belted tires for use during floods. A filtering dam, constructed on the tributaries of major rivers, can create a temporary reservoir in flood zones and is laid across the tributary channel in the form of a trapezoidal prism. The dam is made of cylindrical gabions filled with soil. The shells of the cylindrical gabions are made from interconnected recycled steel-belted tires of the same type. The gabions are laid in layers along the tributary channel, alternating layers with longitudinal and transverse orientations relative to the flow. Longitudinal rows of gabions are spaced apart. This construction allows for the building of protective dams in riverbeds of any configuration and in any geological conditions with minimal material costs.

The authors have also developed a flood protection dam to safeguard populated areas, agricultural, and industrial facilities from flooding. This dam includes interconnected cells with vertical flexible walls made from outer and inner shells. Recycled steel-belted tires of the same type are used as shells, connected by various fastening elements (metal or polymer). The cavity formed by the tires is filled with ballast material (local soil). The shells are reinforced with cross-members made of flexible impermeable material. The upper cross-members are connected by tensioning to anchors, designed as screw piles or braces. The feasibility of using this flood protection dam is due to the increased efficiency of a lightweight structure that can be installed and reinstalled multiple times at various locations with minimal labor costs.

Numerous designs of mudflow protection structures using recycled tires have been developed. The authors analyzed 18 designs from engineers in Azerbaijan, Kazakhstan, Russia, and Georgia that utilize recycled tires [3]. These designs can be divided into four groups: 1) mudflow protection structures where recycled tires are used as damping and cushioning elements;

2) structures primarily consisting of recycled tires connected in blocks with flexible cables and fasteners; 3) structures where recycled tires are variously threaded onto stakes driven into the riverbed or anchored to a foundation; 4) complex mudflow protection structures where recycled tires work in conjunction with horizontal and vertical beams, as well as anchored flexible connections, functioning as permeable, deformable structures. Research shows that the simplest and most reliable designs are those in the third group.

In recent decades, engineers have noted the potential for using recycled tires as structural components for bank stabilization retaining walls [4]. Retaining walls made from recycled tires are threaded onto piles and secured to the foundation with tensioned flexible cables. Some designs use both piles and tensioned flexible cables. The cavities of the tires may be empty or filled with soil or dry ballast.

The authors have developed a device to protect riverbanks from erosion. The bank stabilization structure includes piles placed at equal distances. Recycled tires are threaded onto the piles, with adjacent rows laid in staggered patterns. The cross-section of the piles should be elliptical, matching the cross-section of the through hole formed when laying tires with staggered seams in adjacent rows. After driving the piles, the tires are threaded in rows; for example, the first row is threaded onto the piles such that each tire is threaded onto each pair of piles starting from the second pile, and so on, depending on the design. This results in the staggered placement of tires.

Heavy rainfall, intensified by global climate warming, leads to noticeable erosion processes. There are many design innovations for anti-erosion structures made from recycled tires. The authors analyzed 109 patents for inventions from the former USSR, the Russian Federation, and the Republic of Azerbaijan. These structural solutions can be classified into 5 classes [5]. The first class includes structures made from whole recycled tires [6]. The second class consists of anti-erosion structures made from whole and cut recycled tires [7]. The third class includes anti-erosion structures made from recycled tires cut in various ways. The fourth class consists of anti-erosion structures assembled from blocks of recycled tires. The fifth class includes complex anti-erosion structures where recycled tires are used not only as protective coverings but also as anchoring and reinforcing elements; where elements made from recycled tires are combined with reinforced concrete and other structural elements; and where recycled tires are connected horizontally and vertically with metal cables and used as flexible dams placed across water flows.

V. On the Use of Recycled Railway Concrete Sleepers in the Construction of Protective Structures Against Catastrophic Natural Phenomena

Decommissioned railway concrete sleepers accumulate in large quantities and are often sent for disposal. Currently, there are three methods for recycling concrete sleepers:

– storing or burying them at designated sites and landfills;

– using concrete sleepers in the construction of lightweight building foundations;

– processing concrete sleepers in crushing plants to obtain artificial gravel and scrap metal in the form of broken reinforcement.

Using whole recycled concrete sleepers for constructing protective structures is a highly economical and environmentally friendly approach, as it eliminates the need for costly and energy-intensive processing. Their residual strength is sufficient to effectively counteract the negative forces created by catastrophic and emergency natural phenomena and processes. Numerous designs have been developed by engineer Yu.P. Kozhin, et al. Notable examples include structures for avalanche and mudflow protection [8], retaining walls with various configurations utilizing recycled concrete sleepers [9, 10, 11], bank stabilization structures made from interconnected recycled sleepers [12], and modular frames containing protective plates fixed to counterforts [13], which are shaped like triangular frames. Additionally, there is a design for river regulation aimed at protecting riverbanks from erosion [14].

The authors have developed bank stabilization structures that incorporate recycled concrete sleepers into the shelves of channel (or I-beam) piles. Standard metal channel or I-beam profiles are used as piles. Various mudflow protection structures have also been developed, where horizontal beams in the form of recycled concrete sleepers are inserted onto different notched posts anchored to the riverbed.

The unique mechanical and geometric properties of recycled steel-belted tires and concrete sleepers present engineers with opportunities to create new cost-effective protective structures against various catastrophic phenomena caused by global climate change on Earth.

VI. Conclusions

1. Global warming is accompanied by intense snowmelt and evaporation. The cloud cover accumulated in the atmosphere contains a vast amount of water, which falls as prolonged heavy rainfall, resulting in catastrophic floods, mudslides, landslides, and erosion processes.
2. The most common type of consumer waste consists of recycled automobile and tractor tires. The unique geometric and mechanical properties of steel-belted recycled tires allow for their effective use in the design of protective structures. The authors have developed relatively simple and cost-effective protective structures made from recycled steel-belted tires for use during floods.
3. The authors analyzed 18 designs of mudslide protection structures developed by engineers from Azerbaijan, Kazakhstan, Russia, and Georgia that utilize recycled tires.
4. In recent decades, engineers focused on the potential use of recycled tires as structural components in bank stabilization retaining walls. The authors developed a device for protecting banks from erosion. The bank stabilization structure includes piles placed at equal intervals, onto which recycled tires are threaded, with adjacent rows laid in staggered seams.
5. The authors analyzed over a hundred patents for anti-erosion structures made from recycled tires. These design solutions can be divided into five classes.
6. Decommissioned railway concrete sleepers accumulate in large quantities and are often sent for disposal. The use of whole recycled concrete sleepers for constructing protective structures is highly economical and environmentally friendly, as their residual strength is sufficient to effectively counteract the negative forces created by catastrophic and emergency natural phenomena and processes.
7. The authors analyzed known designs for avalanche and mudflow protection, retaining walls with various configurations using recycled concrete sleepers, and bank stabilization structures made from interconnected recycled sleepers and modular frames securely fixed to counterforts. There is also a design for river regulation intended to protect riverbanks from erosion.
8. The authors developed bank stabilization structures that incorporate recycled concrete sleepers into the shelves of channel (or I-beam) piles. Various mudslide protection structures have also been designed, where horizontal beams in the form of recycled concrete sleepers are inserted onto different notched posts anchored to the riverbed.

Abstract

The Republic of Azerbaijan's climate is changing, and the signs of shortcomings with the water resources are everywhere, and predominantly associated problems are getting increasingly severe. In turn, the synoptic weather systems leading to decreasing low precipitation levels due to climate change have aggravated the country's water scarcity in recent years, as all other environmental relational parts frequencies are meaningfully changing. Most frequently, the reduction in rainfalls persistently affects agriculture, infrastructure, the environment, and ecosystems in many ways. We do not yet know where, when, and how much water sources are lost from water reserves, for instance, the Caspian Sea storage.

Consequently, the country's vulnerable water resources must be carefully monitored in different ways and scales precisely and wisely. It seems that according to the possibilities of technologies, software, and expert forces, it is now time to take executive measures to solve this critical problem of the country comprehensively. Accordingly, multi-platform and multi-purpose monitoring systems are almost immediately required to construct a relevant applied-based nationwide wide-ranging water resources database. Major watersheds must be watchfully experimented with by employing advanced integrated and fused real, near real-time, and intelligent smart monitoring systems directed to advanced machine-deep-learning approaches.

Keywords: multi-purpose monitoring, real monitoring, near-real monitoring, smart monitoring, water resources

I. Introduction

The water crisis in the Republic of Azerbaijan is entering a new pattern where its impacts are becoming visible in the daily lives of millions of people (Safarov et al., 2018). Several strong signs are showing significant changes in the process of reducing water resources, particularly in the semiarid and drought-prone parts of the country with increasing vulnerability to this natural hazard (Safarov et al., 2017). Water scarcity and drought issues are among the biggest challenges facing the country. This phenomenon can be due to the appearance of changes in the frequency of atmospheric systems and less precipitated clouds associated with the precipitation potential in these systems (Rasouli, 2011). The water source of the country is related to the arrival of moist air masses from outside the country, especially from the west, northwest, and occasionally from the southwest (Mammadov et al., 2009; Bayramov, 2020). Clearly, during the past decades, the frequency of occurrence of these systems has decreased, and sometimes, with destructive floods, whenever large amounts of water resources are out of reach of the country. In addition, the river network in Azerbaijan is unevenly distributed over the territory, and, drinking water in Azerbaijan is mainly sourced from such distributed rivers.

The bad news is that the Caspian Sea- the largest landlocked water body worldwide- has been facing a decrease in water and its consequences such as changes in the coastal environment and ecology of the coasts (Rasouli and Imrani, 2023). Various reports indicate that the water level of the Caspian Sea has decreased by 2 meters in recent years and could drop by 9 to 18 meters by the end of the 21st century *(*Lahijani et al., 2023*)*. If we count the effects of climate change and the current water consumption policies to this category, we will witness exponential crises in the country's water resources (Safarov et al., 2020). Water scarcity in Azerbaijan could lead to a complex social-ecological challenge, and various factors contribute to it differently, including agriculture, urbanization, climate change, population growth, land-use change, and an ineffective water management system (Chen et al., 2017).

In such a situation, policymakers and experts in the fields related to water resources science should take fundamental steps for the country's vulnerable water consumption. One of the most important is obtaining accurate information through multipurpose and multimeter monitoring methods. Nowadays, we can refer to real-time, near real-time, and smart-monitoring systems as intelligent measurements of related parameters (Rasouli and Mammadov, 2021). After a detailed knowledge of the quantitative and qualitative characteristics of the water resources, it is possible to witness positive consequences with optimal water consumption policies. Hence, with the aim of systematic access to comprehensive and accurate information and in the category of resources in crisis of the country, it is possible to use modern methods of remote sensing, especially of the types of receiving all data related to water resources at the time having the following:

- ✓ Observation and detection of water data types from natural and non-natural environments of the country,
- ✓ Operating special tools with high technology in the accurate detection of water elements,
- ✓ Recognition of water resources at different temporal and spatial scales,
- ✓ An accurate understanding of water surface changes in the country water basin contexts,

II. Result and Discussion

Real-Time Monitoring Systems (RTMS).

One of the main aims of remote sensing is the observation and detection of dissimilar data types from physical and non-physical environments of the water surfaces (Sharma et al., 2021). Based on the RTMS, special tools with superior technology in water resource elements are vital for our country's current water crises. Each RTMS provides new raw data or higher levels for other information-producing systems. Some scientists believe that any RTMS can be considered the driver of Spatial Information Science (SIS) with the goal of sustainable water resources management policy (Rasouli et al., 2021). An RTMS acts to detect the physical characteristics of an area covered by water by measuring its reflected and emitted radiation at a distance (typically from active or non-active sensors). Since Apollo 17 captured the famous Blue Marble photograph of the earth in 1972, we have had a good idea of "what our planet looks like." Such shots show satellite imagery, real-time cloud cover, precipitation, and many other water-related layers worldwide. Meanwell, the modern remote sensing technique is widely used to delineate surface water bodies, estimate meteorological variables like precipitation, calculate hydrological state variables like soil moisture and land surface characteristics, and estimate fluxes such as evapotranspiration.

In the same way, it is vital to accurately measure the critical conditions of our country's water resources. An example of this type of real-time remote sensing is the NASA meteorology satellite systems. Such systems can monitor not only the atmospheric conditions (for example, cloud characters) covering the country for every 30-minute interval but also check the conditions of the land surface and water resources, for instance, the Caspian Sea changes. Among other real-time sensors of the active type, we can mention the meteorological Doppler Radar, which measures different rainfall parameters as it can estimate the intensity and accumulation of daily rainfall with suitable spatial and diurnal resolutions (Rasouli et al., 2014). In the same way, surface precipitation rate, daily rainfall resolution, and intensity can be produced in 15 minutes. To watch the country's water surface context and changes accurately real-time remote sensing detection is needed (Rasouli et al., 2010). Compared with the traditional methods, the proposed framework is an adaptable remote sensing detection framework for most of the country's water surface observation. Despite the existence of real-time measurement devices, we have the possibility and ability to use the existing real-time systems in a way to solve the water crisis in the declaration.

Near Real-Time Water Sources Monitoring (NRTWSM).

An NRTWSM system could be defined as the observation of water bodies such as lakes, oceans, and rivers from a distance to describe their surface, color, state of ecosystem health, and productivity timely. This kind of remote sensing technology assists in monitoring water quality by detecting parameters such as turbidity, chlorophyll concentration, and temperature. The sensors can identify pollutants and harmful algal blooms in water bodies, helping authorities take timely actions to safeguard water quality and public health, evolving rapidly. Many sensors, for example, most Sentinel (1-6) satellites incorporating applied algorithms, are making significant advancements in water resources applications (EU's Copernicus Programme, 2021). Thus, a broad range of applications of remote sensing in water resources can be summarized under three classes water resources mapping, estimation of the hydro-meteorological state variables and fluxes, and applications of the remote sensing data in water resources management. Under each section, details of the sources of the country's remote sensing data products that could addressed, if any, are also included.

For many years, NRTWSM has been increasingly used as a complementary source of information in water networks and, in many cases, is the only feasible source. Satellite-based sensors are making direct and indirect measurements of nearly all components of the hydrological cycle (Han et al., 2017). These include precipitation, evaporation, lake and river levels, surface water, soil moisture, snow, total water storage, and subsurface water. Accordingly, these sensors currently provide critical information in monitoring the evolution of hazards and their impacts. Although some of these satellite remote sensing products are in their initial stages, there are some advantages and positive signs in their use for NRTWSM. Large spatial coverage and high temporal resolution (sub-daily for geostationary and equatorial orbiting satellites) means they can provide near-nationwide information in near real-time (Liu et al., 2020). These data can be processed and transformed the raw data collected by the sensors into meaningful information for water resources researchers and managers. It may include pre-processing, which involves correcting errors, distortions, and noise caused by the sensors, the atmosphere, and the terrain. NRTWSM allows scientists to record the quantity and qualities of water bodies around the country, which provides information on the presence and abundance of optically active natural water components. Despite the many views and different sensors and methods of applying NRTWSM, users can refer to Sentinel-1 & 6 (active), Sentinel-2, Sentinel-3, and Landsat 8 and 9 as non-passive imagery. NASA's atmosphere section is another example of a near real-time capability that supports interested users in monitoring a wide variety of water-based-created data and parameters (NASA, 2013). These data are made available much quicker than routine image processing allows (Rasouli et al., 2021). Most data products are available within three hours of satellite observation, with imagery generally available 3-5 hours after the observation stage. To access these valuable data in monitoring water resources, researchers only need the specific cases usable for most geographic regions of the country.

Smart Water Resources Monitoring Systems (SWRMS).

In recent years, SWRMS systems have emerged as powerful tools in this endeavor, providing real-time data and actionable insights to promote sustainable water usage and reduce waste (Saqib et al., 2015). Water demand in urban and rural areas countrywide has increased due to population growth and climate change. In today's situation, SWRMS could integrate sensors, meters, and advanced analytics to continuously monitor and analyze water usage patterns within a particular area. Technically, all SWRMS tools can be connected to a central hub and mobile application by providing users with real-time insights into their water resources under the study. By introducing SWRMS, it is possible to leverage the capabilities of the Internet of Things (IoT) to collect and analyze real-time data on water consumption. These systems comprise sensors, meters, and intelligent software that work together to provide a comprehensive view of water usage in the agricultural and residential sectors. SWRMS has many key features and advantages of real-time data, leak detection, usage analytics, remote control, and integration with other IoT devices.

At a controllable SWRMS approach, incorporating into a society-used water consumption offers numerous benefits for homeowners, water utilities, environment water usage, leak prevention, cost savings, and Environmental impacts. At a glance, conserving water through SWMS minimizes the strain on local water resources and reduces energy consumption associated with water treatment and distribution (Palermo et al., 2022). These systems contribute to a more sustainable future by preserving precious water supplies for the next generations. Given these issues, water utilities need a well-planned SWRMS to monitor remotely every part of the water cycle—from sourcing to treatment to delivery to consumption—to respond faster to changing conditions, minimize disruptions, and operate more efficiently. Participants can explore the following areas of interest in this challenge:

- Monitoring of water level and condition (through advanced telemetric devices, drones, or pressure sensors, among others)
- Demand forecasting or monitoring consumption to help manage the pressure and speed of water
- Asset management, detecting leaks, and predictive maintenance
- Staff safety and operational performance; including status reporting like workforce capacity and activities
- Tailored customer service, for example, real-time updates on closures and disruptions, hourly consumption, leak detection, and customer feedback,

In the recent years, several innovations have been made in the field of communications that are transitioning to the Internet of Things with the progression of advancements in technology. In water domain sections, Wireless Sensor Networks (WSN) are one of those independent sensing devices to monitor physical and environmental conditions along with thousands of applications in other fields (Taheria et al., 2020).

III. Conclusion

All water sources in the Republic of Azerbaijan are undergoing significant changes, as the signs of environmental damage can be seen everywhere in our beloved homeland. There are extensive changes in water territories that seem unavoidable in large dimensions. Such changes in water environments could affect industrial sections, agriculture activities, people's health, and the national economy in many ways. To access these aims, meteorologists, climatologists, water scientists, and managers have to watch and get accurate information about the water resources through one unique applicable policy to reduce the disastrous consequences of unintelligent use of limited and vulnerable water resources.

It is now possible to introduce a modern multi-platform, and with dissimilar purposes suited to the country's water resources sections with reasonable time, energy, and costs. Applying advanced image processing methods and informed interpretation of the ending results can lead to the applied pure sciences. The design of timely, purposeful, and multi-purpose decision-making databases can be of considerable help to researchers and managers of water fields.

If truth be told, most water resources are ever-changing meaningfully throughout the country. We have lost some of the lakes during the last few years. The Caspian Sea coastal areas are changing meaningfully and may seriously affect infrastructure, the environment, and ecosystems in many ways:

- In most parts of the country, particularly in Aran County, water resources are declining sharply.
- The Azerbaijan geo-environment must be watchfully monitored employing modern remote sensing technology.
- Advanced image processing is a better way to reach practical and accurate knowledge of water topics and associated environmental matters.
- Some advanced image processing, such as OBIA, Fuzzy, and Machine-Learning / Deep learning, could provide essential water databases for management plans.
- A combination of multi-platforms such as real-time, near-real-time, and smart-monitoring systems is almost immediately required if it is not too late.

Abstract

The tourism destination is always the point of intercrossed interests. The case of seaside resort city of Batumi reveals the Society's aspiration to be sustainable and the local government's intention to cope with ecological and social risks along with tourism industry actions oriented primarily on (as short run as possible) highest profits. The interest conflicts could be overcome by the orientation on the responsible traveler segment. The research presents the relationship between the level of environmental responsibility of the travelers and the level of environmental-friendly actions of the locals, industry and local government. The modern tourism history of the city reveals the changes in the behavior of the citizens, developments in the strategies of the tourism industry actors and the modernization of measures the local government implements. It appears that these changes rely on the changes in the level of responsibility of the city's visitors. Several directions to modernize city's advertisement campaign on the responsible traveler have elaborated.

Keywords: sustainability, responsibility, traveler, city, tourism industry

I. Introduction

The tourism destination could be presented as a set of the relationships between 4 main actors: Traveler, industry, locals and government. It also could be described as a set of dilemmas of sustainable development (see Table 1 below):

Table 1: *Actors and dilemmas of the sustainable development of the city*

Elements of Sustainability			
Tourism Actor	Economic	Social	Environmental
Traveler	Seeks Outstanding Experience	Interacts with locals	Additional load on Environment
Industry	Seeks for profit	Employs and pays	Additional load on Environment
Locals	Seek for vacancies and salaries	Tries to adapt	Seeks for quality of life
Government	Seeks for economic growth	Tries to balance	Tries to regulate

Mohan [3] Used Case study to reveal tourism potential to strengthen the sustainable development in Tobago. One of the recommendations of the research was the action of policymakers as catalysts of the change. It is Quite interesting work because it reveals that the sustainable development goals could be achieved if the stakeholders have the interest to participate in.

Panasiuk [4] discussed the case of sustainable development of the cities under the influence of rising tourist flows. The work is very interesting because it reveals the problems that could be created by overtourism and sets the principles for sustainable urban tourism development policy.

Much interesting work of Lee, Hunter and Chung [2] suggests the idea of smart tourism city – the concept that could overcome one of the dilemmas of tourists-locals conflict. The authors give the solution for one of the issues of sustainability, outline the importance of Information communication technologies and the role of the government in implementation of smart tourism city concept.

Another interesting concept for the city sustainable development that tries to solve conflict between city's economic development goals and necessity to maintain the quality of life for locals is presented in the work of Riffat, Povel and Aydin [6]. The researchers reveal key schemas and solutions for future cities those trying to elaborate the principles the future cities should follow to maintain the harmony between economic and environmental goals.

Day, Morrison and Coca-Stefaniak [1] call for rethinking the approaches to sustainability to cope with challenges that modern world sets for tourism development, especially in the big cities those are characterized by higher level of urbanization and host the higher level of tourist flows. They suggest that interdisciplinary approaches to city development problems could solve the dilemmas of sustainable development.

Pavlic, Portolan and Butorac [5] investigate the importance of principles of sustainability to develop the urban tourism. They use the case of Dubrovnik to reveal the necessity of sustainable approaches to the city's tourism development. The study gives the several recommendations for city tourism policy makers to implement the principles of sustainability.

Tierney, Hunt and Latkova [7] use factor analysis to identify the travelers' attitude to green practices of tourism industry. The authors trace the relationship between requests of travelers and sustainable management decisions in the tourism industry.

The presented research aims to reveal the ways the travelers' environmental responsibility defines the decisions made by tourism stakeholders in the destination. The research uses the case study of city of Batumi – seaside resort located in the south-west of Georgia on the east coast of the black sea. The city's tourism history could be counted since 1881 when the seaside boulevard idea was formed and the city started to implement it. Modern tourism history of the city starts the couple of decades ago as it recovers its popularity at old market segments and gains more and more travelers from new market segments. Today the city of Batumi is the dynamic, developing seaside resort, striving for becoming the tourist city for all seasons, with higher rates of tourist flows and high rates of tourism-related investment. All the dilemmas listed above could be easily observed in the city's performance through the stakeholder analysis.

The research was conducted in two steps: 1) the theoretical framework was created to reveal the ways the travelers' attitude to environmental-friendly behavior and practice influence on the decisions in the city's tourism field; 2) The case of the city of Batumi was discussed following the schema elaborated at previous step; 3) the key conclusions were made.

II. Travelers' environmental responsibility as a key determinant of destination sustainable development

The key idea of development the sustainable tourism destination is that the main incentive, main factor that stimulates the environment-friendly actions and decisions trough the stakeholders of the tourism industry, is the traveler. Similar to the traditional free market signal system, where the consumer sets the requirements for the goods and services, gives signals to the product market and entrepreneurs and those give the signals to resource markets an resource holders, the traveler sets the conditions for environmental-friendly actions, gives signals to the locals, tourism industry and government to change their actions and decisions (see Fig. 1 below).

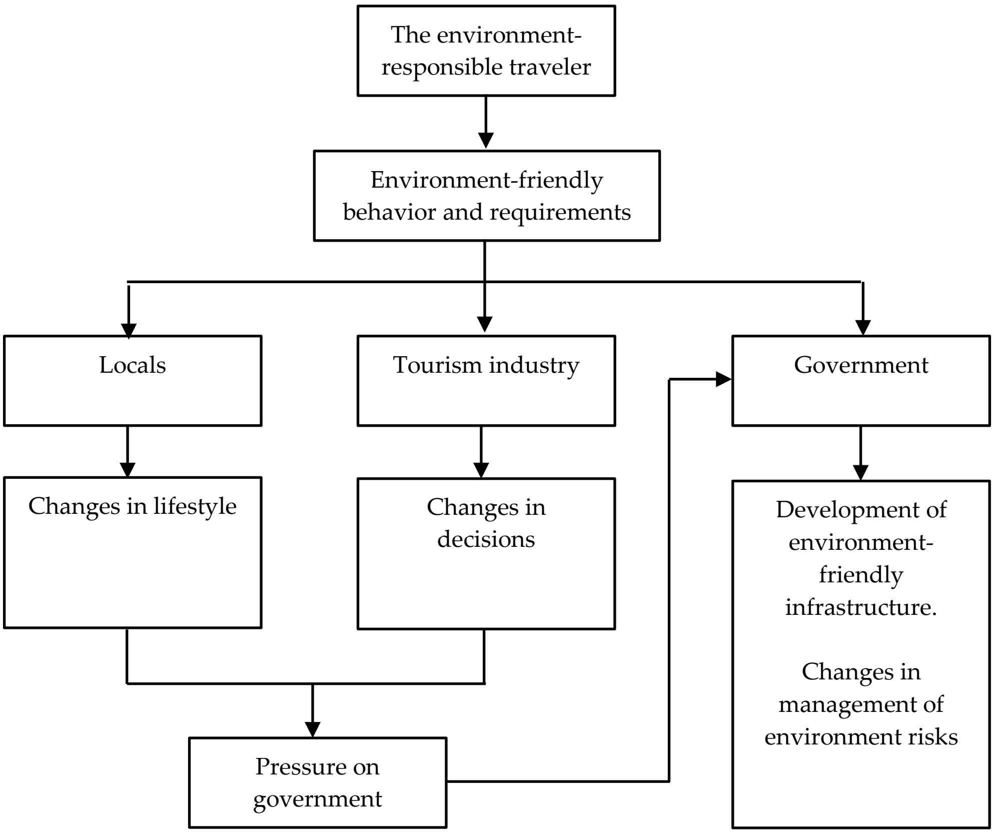

Figure 1: *Traveler as an incentive for environment-friendly actions and decisions*

The modern traveler could be characterized as a person who looks for original experience. Mostly the term "original experience" is associated with the sustainability principles: it implies the respect of local culture, tradition and lifestyle and intends such a behavior that doesn't harm nature. More of that, the modern traveler not only reveals environment-friendly action, it requires it from the others – the traveler makes his/her choices during travel according to the requirements of sustainability. It means, that the destinations those do not meet these requirements will lose their competitive advantages and will be defeated in the long-run period. The modern traveler directs the ways the destinations should be developed in a sustainable manner.

The tourism industry is in the direct relation with the traveler and tries to adapt to the requirements of modern traveler. The adaptation process takes the several forms: implementing the sustainable decisions for waste management, energy and water consumption; pay more attention to the green areas; changing approaches to the construction plan exterior and interior decisions; investing in more sustainable-friendly technologies.

The changes in the behavior of locals are the result of intercultural communication. The intercultural influence is the most latent process that could be revealed (if ever) after the years of interaction, but it is most important one because its influence covers the minds of the population and leads to the changed behavior and creates the context in which all the sustainable-friendly private and public decisions will be perceived as a normal for particular society.

The local government is affected by the traveler in two ways: directly and indirectly. The direct pressure takes the form of raised tourist flows those create the problems with transport infrastructure, utilities, safety, environment, attractions etc. The indirect pressure comes from the locals and the industry trying to urge government to change its tourism policy strategies to meet the new challenges set by modern treveler. In a response the government modernizes all the spheres of city's life – revises city development plans to allow tourism and other superstructure objects to grow; develops the transport infrastructure; modernizes city municipal transport; introduces new systems in a waste, water and electricity supply management; tries to introduce alternative energy projects etc. Another change for the local government is related to the management of the environmental risks as the tourism develops the local safety system conditions, resources and performance are continuously improving to meet and operatively cope with environment crisis issues and problems. Government allocates more financial, human and material resources into the monitoring of environment conditions raising the readiness of the city for different environment crisis situations.

III. The case of the city of Batumi – the travelers changing the city

The city of Batumi hosts the beach tourism travelers from neighbor countries and it was the first and traditional segment of market for the city, but new tourism history of the city reveals the rising importance of cultural tourism during whole year represented by the visitors from both neighbor and Europe-origination, plus important segment of Israeli and Arab-originated travelers. They define the type of influence on the city's tourism stakeholders (see the Figure 2 below):

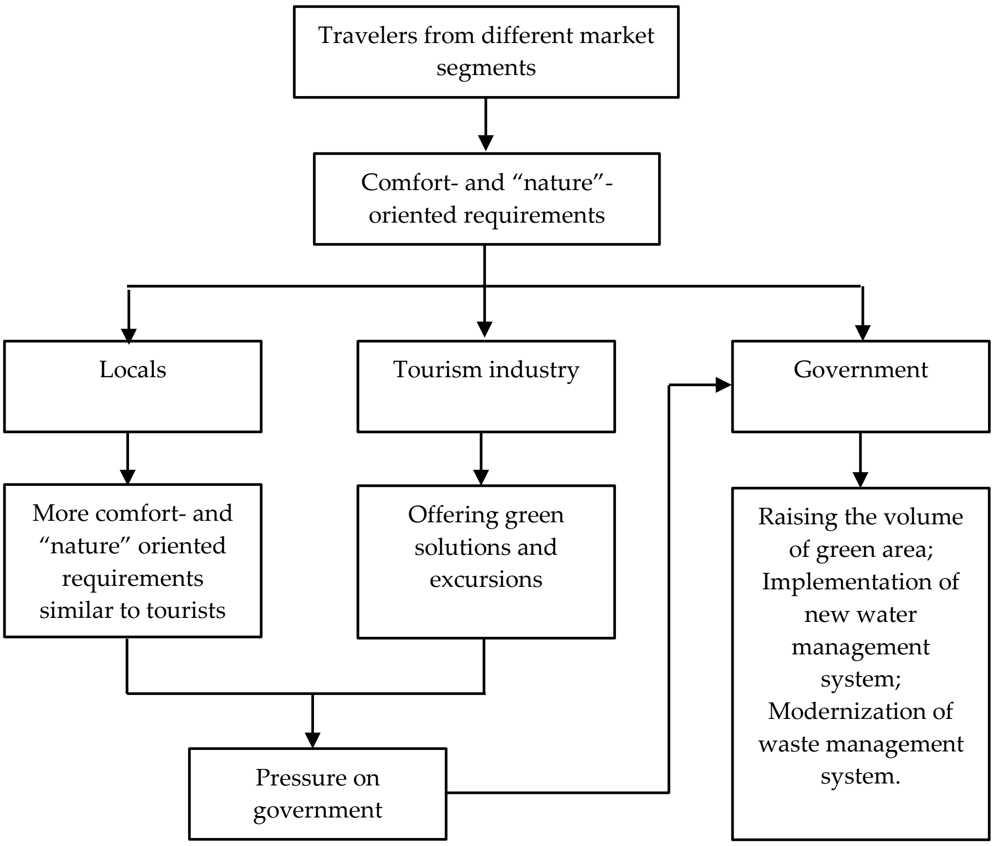

Figure 2: *Tourism stakeholders' adaptation to the Traveler in the city of Batumi*

The modern tourists visiting Batumi are more oriented on the comfort and nature. They look for comfortable, clean apartments near the sea and spend the evenings walking the boulevard and parks; they visit city's Botanical Garden and nearby natural attractions (national parks and villages); They are much familiarized with the city's natural and cultural attractions and enjoy every moment visiting the city. They are aware about local culture and nature and expose it in the communication with the locals and industry.

The industry reacted in a several ways. Huge development firms started the huge construction projects to ensure the sufficient quantity of rooms for rising number of the travelers. The construction boom is continuing now. But the content of such a boom is changing – decades ago the development firms did not play much attention to the sustainability issues – the faster and cheaper the project will be implemented the higher the profit will be gained. But today many development firms start to offer the original projects and the sustainable solutions play one of the important roles in such an offer. The other form of adaptation comes from the small tour-operators, mostly represented by small companies or the individual entrepreneurs those offering the number of nature-type excursions to the visitors. The dozens of such a tour-operators invading the places where the tourists flow making their offers.

The city's government adaptation process is also worth to mention. First of all, the government extends the boulevard. It is the key competitive advantage of the city and as the boulevard stretches its length the new investment and tourists rising flows follow it. Second, the government raises its investment in the safety of the seaside – it implements the beaches protecting measures, improves the quality and rises the quantity of the resources to rise the readiness of the safety system to effectively cope with crisis situations (storms, soil washing etc.). Third, It implements new water management and waste management systems in the city; Fourth, it rises the green area in the city by the construction of new parks.

The reaction of the locals is quite interesting. Similar to the tourists, the locals are more tend to the comfort and nature. It is quite typical for locals to reshape their yards in a green manner, to use less private transport, to "escape" in the villages etc. Couple of decades are not enough to change the locals' attitude and the above-mentioned changes could be discussed as the negative reaction on the rising tourist flow, attempt to rise the distance from tourists, but the fact is that, positively or negatively, tourists stimulate the locals to be more sustainable.

IV. Conclusions

In a modern Urbanized world, the issue of the sustainability of the cities, especially under the rising tourist flow, is the most important question for the city development sphere. Most researches in thew field recommend the government actions but pay less attention on the changes in the travelers' minds that could be the solution for all the sustainable goal dilemmas the cities face today.

The environment-responsible traveler affects on all the stakeholders of the tourism in the city – locals, industry and government. More of that, the local government is under the double pressure – it is affected by the traveler and is affected by the locals and industry those previously affected by the traveler also.

The modern tourism history of the city of Batumi reveals the changes the changed-mind travelers stimulate: The industry starts to offer more green solutions ion construction projects and more green excursions; local government modernizes the waste and water management systems, raises the volume of green area in the city and improves the readiness to natural crisis; the locals also start to behave more sustainable.

ENVIRONMENTAL RISK MANAGEMENT IN THE STRUCTURE OF GLOBAL RISK ASSESSMENT

Daria Maltseva, Olga Safonova, Daniil Fedotov

•

Saint Petersburg State University, RUSSIA
buenafiesta@mail.ru

Abstract

This article examines the role of environmental factors in contemporary global politics and economics. The authors analyze the main environmental hazards, including climate change, natural disasters, biodiversity loss, and natural resource depletion. Statistical data on the impact of these issues on various aspects of society are presented. Particular attention is paid to methods of assessing and managing environmental challenges, including the use of various indices and indicators. The article emphasizes the importance of an integrated interdisciplinary approach to hazard analysis and the need to consider socio-economic factors. The authors discuss risk management strategies, including preventive measures, adaptation, and mitigation. In conclusion, recommendations are offered for enhancing environmental policy, including strengthening the regulatory framework, developing infrastructure, and involving various stakeholders in the environmental risk management process.

Keywords: environmental risks, climate change, natural disasters, biodiversity, risk management

I. Introduction

Environmental factors play a significant role in modern global politics. Scientific and technological progress and increasing human impacts have led to adverse environmental changes, including resource depletion, decreased biodiversity and an increase in natural disasters. This forms new ideological patterns and behavioral strategies at the individual and institutional levels [1].

The modern natural environment is in a state of ecological crisis, characterized by long-term unfavorable changes in the biosphere. There is a steady trend towards deterioration of the environmental situation globally and locally. Some researchers believe that humanity exists in a period of permanent eco -catastrophes - critical states of ecosystems leading to their change or destruction [2][3].

The analysis shows a correlation between the environmental crisis and the aggravation of socio-economic and political risks. U. Beck [4] focused on the need for international cooperation in the field of environmental safety.

According to the Center for Research on the Epidemiology of Natural Disasters, in 2022 there were 387 natural disasters, causing 30,704 deaths and affecting 185 million people [5]. Economic damage is estimated at US$223.8 billion. A comparative analysis with 2021 (10,492 dead, 101.8 million injured) reveals a trend toward escalating risks.

- The most significant natural disasters of 2022:
- Heat wave in Europe: 16,305 deaths
- Drought in Uganda: 2465 deaths
- Floods in Pakistan and India: 1,739 and 2,035 deaths respectively
- Research indicates the uneven distribution of social costs of natural disasters [6][7] with the

predominant vulnerability of rural areas [8][9].

Analysis of social vulnerability to environmental disasters reveals a correlation with the economic development of territories. Research shows that low-income groups are at increased risk due to housing inequality and limited access to evacuation and recovery resources [10].

Statistics show that people in the poorest countries are 6 times more likely to suffer from emergencies [11].

The economic costs of environmental disasters in 2022 amounted to US$223.8 billion. During the period 1998-2017. financial losses from natural disasters increased by 151% [5].

According to the Allianz Global Corporate & Specialty (AGCS) study, based on assessments of 2,712 experts from 94 countries, climate change and natural disasters are among the top risks for government and business, along with cyber threats and macroeconomic factors [12].

- Climate change has a multifaceted impact on the global economy and social sphere, as evidenced by a number of studies and statistics.
- Food Security : According to Global Commission on Adaptation (2019), if the trend towards an increase in average temperatures of 1.5-3°C continues, a 30% reduction in crop yields is expected by 2050 [13]. This comes against the backdrop of a projected 50% increase in global food demand, which could lead to a significant increase in global hunger.
- Water resources: According to the UN World Water Development Report (2021), between 2 and 4 billion people suffer from water shortages on a permanent or seasonal basis [14]. It is predicted that by 2030, humanity will face a 40% water shortage if current rates of economic development continue. WHO Global Water, Sanitation and Hygiene Annual Report (2022) indicates that 1.4 million deaths each year are attributable to lack of consistent access to quality water and sanitation [14].
- Health: A study published in The Lancet Planetary Health (2022) shows that air pollution causes more than 6.5 million deaths each year, and water pollution causes 1.4 million [15]. The World Health Organization predicts that climate change will cause 250,000 additional deaths annually from 2030 to 2050 [16].
- Economic impact: The World Bank predicts that for the Middle East and North Africa, by 2050, the economic cost of water shortages caused by climate change could amount to 6-14% of the region's GDP.

A study presented at the World Economic Forum (2022) indicates that heat stress could reduce total hours worked by more than 2% globally by 2030, equivalent to a potential economic loss of US$2.4 trillion [17].

Agriculture: UN World Water Development Report (2023) notes that about 25% of the world's arable land experiences economic water stress, which is due less to hydrological constraints than to institutional and economic factors [18].

These data demonstrate the complex and interconnected nature of the impact of climate change on various aspects of the global economy and social development. They emphasize the need for an interdisciplinary approach to solving environmental problems and the development of adaptation strategies at the national and international levels.

The state of the environment and the general trends in the dynamics of its development largely determine the vector of development of the human community and states, which actualizes the need to develop a system of strategic political management for a timely response to changes in biogenic constants and leveling environmental risks. The multifaceted nature of environmental problems indicates that mechanisms that can counter socio-economic and political risks are also important for their solution.

Among the global environmental risks on a scale of the next 10 years, the following types are distinguished:

- Climate change:

An increase in temperature above the annual average from spring to autumn increases the risk of droughts, which negatively affects the moisture content of agricultural land and crop yields [19].

Accelerated melting of glaciers poses a serious threat to coastal areas [20].

The rate of sea level rise has doubled over the past 30 years, and this trend is likely to continue.

- Natural disasters:

According to the UN, over the past 50 years the number of natural disasters has increased 5 times [21].

In the Russian Federation, according to the Ministry of Emergency Situations, from 2016 to 2022 the number of natural emergencies increased from 42 to 78 cases [22].

In 2022 in Russia, the greatest threat was posed by hydrological (floods, floods) and meteorological (storms, hurricane winds) phenomena.

The problem of forest fires, threatening more than 40% of the territory of the Russian Federation, is getting worse [23].

- Biodiversity change:

About 1 million species of plants and animals are on the verge of extinction in the coming decades [24].

The World Meteorological Organization predicts that at 2°C warming, the number of species at risk of extinction will be 30% higher than at 1.5°C warming [24].

Warming of 1.5°C could destroy up to 90% of coral reefs, and warming of 2°C could destroy up to 99% [1].

The loss of species disrupts the balance of local ecosystems, affecting agriculture, livestock farming and fishing.

- Natural resource crisis:

The world's population reached 8 billion in October 2022, increasing the demand for resources [25].

At the current level of consumption, proven gas reserves will last for 52 years, oil – for 47 years, coal – for 130 years [25].

The transition to green energy carries risks of depleting rare metals and elements needed to produce solar panels, wind turbines and electric vehicles.

The uneven geographic distribution of these resources could hamper the global transition to low-carbon technologies.

- Anthropogenic influence:

The CO2 content in the atmosphere is 150%, CH4 (methane) – 264%, N2O (nitrogen oxide) – 124% of pre-industrial levels [25].

The influence of CO2 on climate lasts for centuries, in contrast to CH4, which exists in the atmosphere for 9-10 years [26].

High concentrations of greenhouse gases are accelerating climate change, which could lead to faster melting of polar ice caps, rising sea levels and an increase in the frequency of extreme natural events [27].

These data highlight the interconnectedness and complexity of environmental problems that require the development and implementation of effective strategies at the global and local levels to minimize negative impacts and adapt to changing conditions.

It is also important to note that the problem is the nonlinear nature of the development of environmental risks, which implies more difficult to predict dynamics of environmental changes under the influence of various factors, as well as the emergence of the issue of accumulation of risk potential over time [28].

The risk of ineffective human action to solve the problem of climate change in recent times is also quite high. A confirming circumstance is the fact that despite the actions taken by the international community, keeping the level of climate change at the level of 1.5 ° C set by the Paris

Agreement seems practically unattainable, which increases the risk of negative consequences for the planet [29]. Despite some signs of environmental progress, at current dynamics and full implementation of national climate commitments until 2030, temperature changes will at best be kept to 2.4-2.8°C by the end of the century, demonstrating the need significant revision of the measures taken due to their lack of effectiveness [30].

II. Methods

To predict the development of environmental risks, analyze the overall effectiveness of actions taken, as well as their long-term planning, various indicators and indices that make up risk assessment systems are important.

Environmental Risk Assessment – Environmental Risk Assessment – aims to identify and analyze potential environmental risks arising from human activities that may cause harm to people and/or ecological systems [31].

The Global Climate Risk Index analyzes and ranks the extent to which countries and regions are exposed to climate-related extreme weather events (storms, floods, heat waves, etc.) [32].

Environmental Performance Index , which analyzes the overall performance of states' environmental policies in the context of three main categories: environmental protection, ecosystem viability and climate change [33]. This rating also ranks the states in question according to the degree of their environmental efficiency: for example, in the 2022 report, Russia ranks 112th in the overall rating of 180 countries [33].

The Green Growth Index assesses countries' progress towards achieving sustainable development goals across four dimensions: resource management, natural capital protection, green economic opportunities and social inclusion [34].

The Global Green Economy Index measures the performance of the green economy across four key dimensions: climate change, industrial decarbonization, ESG investing and environmental stewardship [34].

The World Risk Index analyzes the risk of natural disasters resulting from extreme natural events, taking into account a country's exposure and vulnerability to risk [35]. The above indices make it possible to evaluate certain components of the general environmental state of countries and regions of the world.

A more comprehensive approach is featured in the Sustainable Development Goals Index compiled by SDSN and Bertelsmann Stiftung [36]. It is based on the 17 socio-ecological development goals outlined in the 2030 Agenda adopted in 2015 by the UN General Assembly [37]. The most difficult to achieve are the following environmental sustainable development goals (SDGs): SDG 12 – transition to sustainable consumption and production patterns, SDG 13 – combating climate change, SDG 14 – conservation of oceans and seas, sustainable use of marine resources, SDG 15 – protection terrestrial ecosystems and biodiversity [37]. All of these goals relate to the environmental sphere, which demonstrates the high complexity of the practical implementation of environmental actions by states around the world. This problem is exacerbated in low-income countries due to the lack of infrastructure and mechanisms to deal with environmental problems, which demonstrates the greater environmental vulnerability of less developed countries.

III. Results

A comprehensive multidisciplinary risk analysis should include not only an assessment of the influence of a certain factor, but a set of various risk determinants and their influence on each other [39]. Thus, the factor of climate disasters in 2020 was significantly aggravated by the development of the Covid -19 pandemic, which caused a high burden on healthcare systems, energy supplies, and the work of emergency services in many countries [38].

It is also worth noting that when assessing overall environmental risk, it is important to consider responses, as they play a key role in achieving potential outcomes and are also determined by political and economic components [39]. This approach provides a holistic perception of real or predicted risk, since it explains why, in some cases, decision makers do not take action to reduce risk: the reason may be possible reputational risks, insufficient funding, untested technological solutions, etc. [40].

Decision-making, in turn, can be accompanied not only by positive consequences and risk mitigation, but also by aggravation of current problems, including through numerous compromises and associated benefits for the actors, which can change the overall nature of the risk and its complexity. Thus, taking into account socio-economic, political factors, regional characteristics, and the interaction of management systems at different levels makes it possible to more accurately assess environmental risks and conceptualize strategies to mitigate potential negative effects.

Environmental risk management consists of several stages of risk management:

1. primary analysis and identification of risks;
2. determination of the main directions for their leveling;
3. assessment of probability, influencing factors, probable damage;
4. development and planning of risk reduction measures [41].

Natural disaster risk management must be based on a structural understanding of the formation and evolution of natural disasters, disaster mitigation and subsequent recovery. Taking into account the factors mentioned above, as well as the use of developed geotechnical and environmental engineering systems, should help improve the assessment and identification of natural risks and reduce disaster risk in general [42]. It is also important to analyze the social context, structural forces and conjunctural factors that make up the contextual framework of the problem under study.

A separate factor that can also potentially have a significant impact on managing environmental risks and reducing the negative consequences of climate change is the use of information systems and artificial intelligence. In the context of digitalization, the competent use of modern technologies can help solve existing problems and achieve sustainable development, but this strategy also has potential adverse consequences in case of irresponsible use of information systems [43][44].

In general, risk management methods are divided into 4 categories [45]:

1. risk avoidance methods;
2. methods of risk localization;
3. risk dispersal methods;
4. risk compensation methods.

In relation to environmental issues, it is worth noting that the option of evading an unfavorable natural phenomenon is not always possible, therefore it seems important to pay attention to procedures for minimizing negative effects. At the same time, some environmental risks can be mitigated by localization if they are clearly identified, the source is determined, and ways to influence the process are established. Risk reduction also occurs through the dissipation method when distributing areas of responsibility between various actors and structures, including political organizations, business structures, non-profit associations and individual local communities. Methods for compensating for environmental risk involve the development of strategic planning to predict scenarios for the development of natural and man-made disasters and the development of tools for their prevention.

An environmental risk management strategy typically reflects one of several principles [4]:

1. the zero-risk principle, based on the premise that there is no harm to the environment and there is no need to do anything;

2. the principle of minimal risk, which implies the development of options for minimal impact on the biosphere;

3. the principle of balanced risk, which takes into account the anthropogenic factor and implies the implementation of measures to reduce negative effects on the natural environment and potential dangers to the population;
4. the principle of acceptable risk, which is based on an assessment of the costs and benefits of certain business strategies; this principle often leads to a conflict of economic and environmental interests.

In this case, the most effective is the balanced risk approach, which allows one to assess the degree of negative impact on the environmental situation at the national, regional or local level and develop a set of measures to prevent and minimize possible negative effects, as well as reduce the impact of adverse anthropogenic factors.

Environmental risk management includes both a preliminary risk assessment and forecasting of possible scenarios for its implementation, as well as the use of preventive measures to counter the risk, as well as measures to mitigate the consequences. In this case, when forming a strategy for dealing with the risks of natural disasters, three stages of the life cycle of a natural disaster will be taken into account:

1. pre-event stage: assessment of potential impact and development of preventive measures;
2. post-disaster response: a phase that facilitates the strategic mobilization of resources and technical support regarding previously identified critical aspects;
3. post-event stage: assessment of the damage caused by the disaster, measures to prevent its socio-territorial consolidation and accelerate recovery processes.

Depending on the phase of the natural disaster cycle, the following options for management activities in relation to natural disasters can be distinguished:

- prevention and minimization: a type of preventive measures aimed at significantly transforming or eliminating certain areas of risk in order to prevent the occurrence and development of adverse consequences;
- recovery: in the event of a disaster that has already occurred, measures are taken to restore infrastructure and repair damaged material objects;
- compensation: measures aimed solely at redressing damages through payments to injured people.

For accurate results of forecasting environmental risks, it is important to assess in advance the degree of vulnerability to extreme events. One of the factors that increases the vulnerability of an area and the uneven distribution of disaster risk is socio-economic inequality. Poor and marginalized populations often live in areas more prone to natural disasters and therefore face greater risks to life, health and finances; Education and age factors greatly influence the level of awareness of what needs to be done in the event of a disaster, and also affects the ability to access warnings, understand them and respond correctly - for example, older people often need additional support in emergency situations Social vulnerability affects not only behavioral responses to natural disasters, but also the ability to recover after it. Therefore, taking into account heterogeneity in society is important for correct analysis of the distribution of potential environmental risk and recovery trajectories.

Also an important part of the work on environmental risk management is the implementation of adaptation policies to prepare for the inevitable consequences. For its implementation, it seems important to develop strategic management at the state and regional levels, taking into account an understanding of the geographical, climatic, socio-economic and other characteristics of the territory. Increasing resilience, a developed system for preventing and responding to the most common natural disasters in the region, and an active information and communication policy aimed at increasing public awareness of behavior in the event of an emergency will reduce socio-economic risks in the event of environmental disasters.

To summarize, it can be argued that today environmental problems are associated with significant social, economic and political risks. Climate change and the increase in natural disasters - floods, droughts, hurricane winds and record temperatures - threaten the food security of individual states and world regions, for example, East Africa. The problem of ensuring access to water in the countries of the Middle East and North Africa also remains. The lack of constant access to water and necessary sanitation conditions increases the risk of epidemic outbreaks of various diseases. Also, in conditions of insufficient resources, geopolitical tension arises between states, which reduces the level of security in the region. Macropolitical and economic factors such as geo-economic confrontation and military conflicts are additional catalysts for environmental problems.

Integrated environmental risk management involves primary analysis and identification of risk, taking into account the influence of a combination of various factors on it, identifying directions for their leveling, designing possible risk scenarios and assessing the likelihood of their occurrence, as well as the likely consequences, taking measures to counter risks and minimize them consequences. An important role is played by forecasting and the scenario method, which allows one to calculate the possible effects of a potential environmental disaster or catastrophe, as well as determine their impact on the aggravation of other current or upcoming crises. The implementation of predictive models, scenario analysis and integrated data collection mechanisms into environmental risk management will improve the ability to effectively prevent and mitigate emerging environmental risks. In recent years, the role of modern technologies and machine learning in risk management has also increased.

IV. Conclusion

An important area within which it is worth developing a risk management system at various levels is adaptation to the consequences of the crisis and mitigation of the consequences. Since not all environmental risks can be prevented, strategic planning should include development in conditions of environmental crisis with minimal damage. Measures to create and regularly modernize infrastructure that is somewhat resilient to climate change and to introduce renewable energy sources seem to be effective.

Improving the regulatory framework is also a significant stage in the development of the state's environmental policy. Regulations and strategic planning documents with mandatory, clearly defined standards and environmental performance indicators, as well as strict liability measures, are designed to ensure effective environmental protection. Increasing the effectiveness of measures taken is possible through the development of environmentally oriented interaction between authorities at various levels, business structures, non-profit organizations and associations, individual local communities and groups and civil society.

In conditions of geopolitical uncertainty and rapidly changing environmental conditions, as well as high socio-economic costs of unfavorable environmental conditions, priority should be given to the use of methods to anticipate and counter possible risks and minimize future negative effects. Environmental problems belong to the category of long-term risks, which complicates their management due to the difficulty of reaching a compromise in making political decisions, the consequences of which will manifest themselves after a certain time and at the moment may not seem to be of sufficient priority to the political and economic elite. More active involvement of the scientific community and practitioners of strategic risk management in the decision-making process is potentially intended to help find a compromise and limit the negative anthropogenic impact on the environment.

Successful Russian practices that demonstrate a new level of risk management deserve special attention in the context of environmental risk management. One of the significant steps towards managing climate change is the new Russian Climate Doctrine adopted in October 2023, according to which Russia must achieve carbon neutrality by 2060. It is important to note the features that form the basis of the new doctrine: special attention to NPOs, public organizations and business. The need to involve different structures and communities in addition to the state itself is emphasized, since the problem of climate change cannot be solved solely by one actor. For future changes, it is clear that the new doctrine means the prolongation of existing federal projects in the field of nature protection and climate change. And non-profit and public organizations will have to replicate the successful practices of climate policy programs. For example, the reforestation campaigns “Garden of Memory” and “Save the Forest,” which have planted more than 220 million trees throughout Russia since 2019, will likely develop and transfer the experience gained internationally.

Based on the practices listed above, a number of common themes should be identified for animation in other industries, both within the state and for the world as a whole.

1. Involving all key actors in network interaction in environmental risk management: government, business and the non-profit sector;

2. Non-triviality and creativity in environmental issues allows us to most successfully involve people in the agenda, which is necessary for successful risk management in the field of ecology;

3. The integration of innovative computer technologies and artificial intelligence allows for the implementation of higher quality and more effective projects and programs for assessing and managing environmental risks.

Thus, it should be noted that at the present stage, the risk potential of environmental problems is regularly increasing, which determines the actualization of the development of strategic risk management to manage environmental risks both at the global level and at the level of individual states and regions. As it was established, to counter them, it is necessary to implement a set of political, legal, economic and social measures to develop the state’s environmental policy. In conditions of high socio-economic costs of unfavorable environmental conditions, an important role in environmental risk management is given to the use of methods to proactively, minimize relevant risks and level out possible negative effects.

Abstract

Some results of a study of the variability of the number of days with hail in the warm half of the year (April-October) for 22 weather stations in Georgia from 1941 to 2021, on average for five climatic zones, which includes four climatic groups according to the Köppen classification, are presented. Zones I and III – warm oceanic climate/humid subtropical climate (Cfa): Zone I – Kutaisi, Mta-Sabueti, Senaki, Shovi, Zugdidi; Zone III – Kvareli, Lagodekhi, Telavi. Zone II – warm continental climate/humid continental climate (Dfa): Bolnisi, Gori, Khashuri, Marneuli, Pasanauri, Stepantsminda, Tbilisi, Tianeti. Zone IV – temperate oceanic climate (Cfb): Bakhmaro, Chakvi, Khulo. Zone V - temperate continental climate/ humid continental climate (Dfa): Bakuriani, Borjomi, Tsalka. The statistical characteristics of the following parameters were studied. H(I)…H(V) - average number of days with hail per meteorological station in the warm half of the year for climatic zones I...V, respectively. H(I-V) - average number of days with hail per meteorological station for all climatic zones. H(I)'…H(I-V)' - mean per decade rate of change of the H(I)…H(I-V) in 1941-1950 … 2011-2021. In particular, the following results were obtained. The smallest range of changes in H values is observed in the first climatic zone (0÷1.8), the largest - in the fifth (0÷8.3). The linear correlation between the studied parameters between individual zones vary from 0.27 (pair H(I) - H(IV), negligible correlation) to 0.55 (pairs H(II) - H(III) and H(II) - H(V), moderate correlation). The variability of the average ten-decade number of days with hail per weather station change from 0 (Zone IV, 2011-2021) to 5.9 (Zone V, 1941-1950). Trend of the mean number of days with hail per meteorological station year for all climatic zones in Georgia in 1941-2021 is quite satisfactorily described by a fourth power polynomial. The variability of H(I)'…H(I-V)' change from -1.48 in 1941-1950 to 2.09 in 2011-2021 (Zone V).

Keywords: natural disaster, hail, Köppen climate classification, statistical analysis

I. Introduction

Georgia is one of the most hail-prone countries in the world. Therefore, in this country, many works are devoted to the problem of hail damage, the basis of which is hail climatology. The study of the number of days with hail, both in general in Georgia and in its individual regions, has been carried out for many decades [1-11]. In particular, the features of the distribution of the number of days with hail in the warm half of the year for 15 climatic zones of Georgia in the period 1941-1990 were studied [3,11], data on damage from hail storms are provided [5,6,8,11], the variability of the number of days with hail and the connection of this variability with aerosol pollution of the atmosphere have been studied [11], etc.

In 2022-2023, work was carried out to prepare [12,13] and create [14] a systematized catalog for five types of natural disasters in Georgia (landslides, mudflows, hurricane winds, floods and hail).

In particular, using the data from this catalog, work was carried out on a statistical analysis of the number of days with hail in Georgia in 2006-2021 [15], analysis of damage from hail to agricultural crops in Kvemo Kartli (Georgia) [16], studying of long-term variability in the number of days with hail in Tbilisi (1891-2021) [17] and forecasting this variability until 2085 [18].

Our last paper [19] presents some results of a statistical analysis of data from 30 meteorological stations of Georgia on the number of days with hail in the warm half of the year in 1941-2021. In particular, the following results were obtained: data on the average and maximum values of the number of days with hail in 1941-2021, 1941-1980 are provided (first time period) and 1981-2021 (second time period); correlations between the studied parameters for the specified time periods were studied; it was found that in the second period of time, compared to the first, at 21 stations there is a decrease in the average number of days with hail, at 8 stations this number does not change, and only at one station there is an increase in the average number of days with hail; the dependence of the average and maximum number of days with hail on the terrain height was studied for 24 meteorological stations located at a level of less than 1500 m for the specified time periods; it was found that in the second period of time, compared to the first, the tightness of the correlation between the number of days with hail and the altitude of the area weakens.

This study is a continuation of work [19]. Some results of a study of the variability of the number of days with hail in the warm half of the year (April-October) for 22 weather stations in Georgia from 1941 to 2021, on average for five climatic zones, which includes four climatic groups according to the Köppen classification, are presented below.

II. Study area, material and methods

Study area is Georgia and their five climatic zones, including four climatic groups according to the Köppen classification (Fig. 1, Table 1).

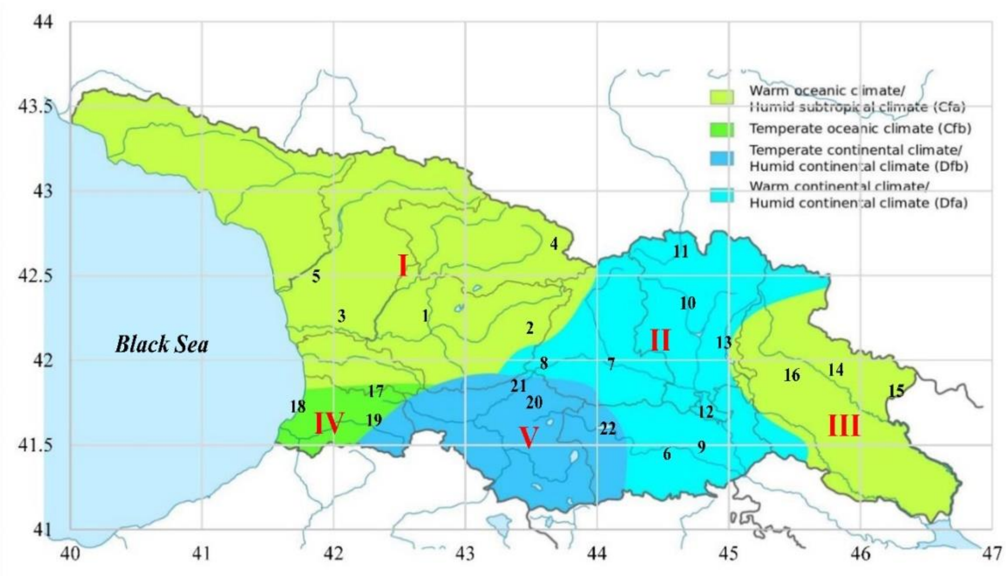

Figure 1: *Köppen climate classification map of Georgia.*
https://commons.wikimedia.org/wiki/File:Köppen_climate_classification_map_of_Georgia.svg

Table 1: *The number of meteorological stations, their coordinates, altitudes and the number of zones of their location (Fig. 1).*

N	Zone	Location	Lat, °N	Lon, °E	H,m	N	Zone	Location	Lat, °N	Lon, °E	H,m
1	I	Kutaisi	42.27	42.70	120	12	II	Tbilisi	41.70	44.83	437
2	I	Mta-Sabueti	42.20	43.50	2470	13	II	Tianeti	42.11	44.97	1100
3	I	Senaki	42.27	42.07	28	14	III	Kvareli	41.95	45.82	450
4	I	Shovi	42.70	43.68	1520	15	III	Lagodekhi	41.82	46.28	450
5	I	Zugdidi	42.51	41.87	100	16	III	Telavi	41.92	45.48	490
6	II	Bolnisi	41.45	44.54	550	17	IV	Bakhmaro	41.85	42.33	1950
7	II	Gori	41.98	44.11	588	18	IV	Chakvi	41.73	41.73	30
8	II	Khashuri	41.99	43.60	680	19	IV	Khulo	41.65	42.31	1044
9	II	Marneuli	41.49	44.80	420	20	V	Bakuriani	41.75	43.53	1700
10	II	Pasanauri	42.35	44.69	1050	21	V	Borjomi	41.85	43.41	850
11	II	Stepantsminda	42.65	44.64	1750	22	V	Tsalka	41.60	44.09	1450

As follows from Fig. 1 and Table 1, the distribution of meteorological stations by climatic zones is as follows. Zones I and III – warm oceanic climate/humid subtropical climate (Cfa): Zone I – Kutaisi (1), Mta-Sabueti (2), Senaki (3), Shovi (4), Zugdidi (5); Zone III – Kvareli (14), Lagodekhi (15), Telavi (16). Zone II – warm continental climate/humid continental climate (Dfa): Bolnisi (6), Gori (7), Khashuri (8), Marneuli (9), Pasanauri (10), Stepantsminda (11), Tbilisi (12), Tianeti (13). Zone IV – temperate oceanic climate (Cfb): Bakhmaro (17), Chakvi (18), Khulo (19). Zone V - temperate continental climate/ humid continental climate (Dfa): Bakuriani (20), Borjomi (21), Tsalka (22).

The work used catalog data [14] on the number of days of hail in warm period of year (April-October) for the above indicated meteorological stations in 1941-2021.

In the proposed work the analysis of data is carried out with the use of the standard statistical analysis methods of random events and methods of mathematical statistics for the non-accidental time-series of observations [20-22].

The following designations will be used below: Mean – average values; Max - maximal values; Min – minimal values; St Dev - standard deviation; R^2 – coefficient of determination; R – coefficient of linear correlation; α - level of significance; the difference between two average values was determined using the Student's criterion with $\alpha \leq 0.05$; K_{DW} – Durbin-Watson statistic. The curve of trend is equation of the regression of the connection of the investigated parameter with the time at the significant value of the determination coefficient and such values of K_{DW}, where the residual values are accidental. If the residual values are not accidental the connection of the investigated parameter with the time we will consider as simply regression.

The degree of correlation was determined in accordance with [20]: very high correlation ($0.9 \leq R \leq 1.0$); high correlation ($0.7 \leq R < 0.9$); moderate correlation ($0.5 \leq R < 0.7$); low correlation ($0.3 \leq R < 0.5$); negligible correlation ($0 \leq R < 0.3$).

H(I)…H(V) - average number of days with hail per meteorological station in the warm half of the year for climatic zones I...V, respectively. H(I-V) - average number of days with hail per meteorological station for all climatic zones. H(I)'…H(I-V)' - mean per decade rate of change of the H(I)…H(I-V) in 1941-1950 … 2011-2021.

III. Results

The results in Fig. 2-5 and Table 2,3 are represented.

In Fig. 2 time-series of the mean number of days with hail per meteorological station in the warm half of the year for climatic zones in Georgia in 1941-2021 are presented. In Table 2 statistical characteristics of Fig. 1 data is represented.

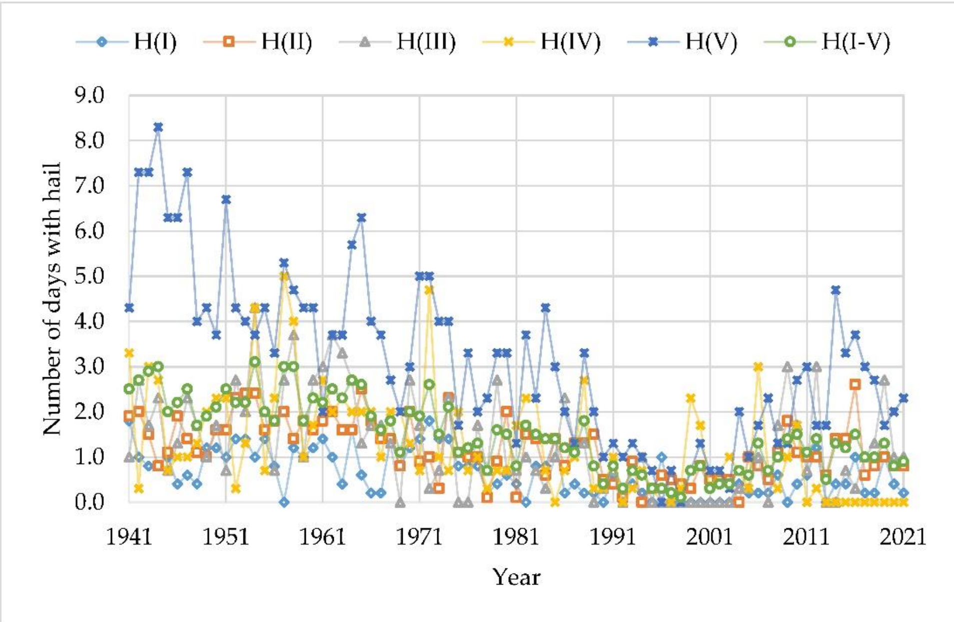

Figure 2: *Variability of the mean number of days with hail per meteorological station in the warm half of the year for climatic zones in Georgia in 1941-2021.*

Table 2. *Statistical characteristics of the mean number of days with hail per meteorological station in the warm half of the year for climatic zones in Georgia in 1941-2021. R_{min} = 0.22, α = 0.05*

Variable	H(I)	H(II)	H(III)	H(IV)	H(V)	H(I-V)
Max	1.8	2.6	4.3	5.0	8.3	3.1
Min	0	0	0	0	0	0.1
Mean	0.6	1.2	1.3	1.2	3.1	1.5
St Dev	0.51	0.64	1.09	1.17	1.88	0.79
	Correlation Matrix					
H(I)	1	0.46	0.38	0.27	0.47	0.61
H(II)	0.46	1	0.55	0.33	0.55	0.73
H(III)	0.38	0.55	1	0.36	0.41	0.71
H(IV)	0.27	0.33	0.36	1	0.37	0.66
H(V)	0.47	0.55	0.41	0.37	1	0.85
H(I-V)	0.61	0.73	0.71	0.66	0.85	1

As follows from Fig. 1 and Table. 2, the distribution of the mean number of days with hail per weather station on the territory of Georgia is quite uneven. In particular, the smallest range of changes in H values is observed in the first climatic zone (0÷1.8), the largest - in the fifth (0÷8.3). In general, in Georgia the H values vary from 0.1 to 3.1. Average values of H changes from 0.6 (first zone) to 3.1 (fifth zone). Mean value of H(I-V) is 1.5.

In general, the linear correlation between the studied parameters is significant. At the same time, between individual zones the R values vary from 0.27 (pair H(I) - H(IV), negligible correlation) to 0.55 (pairs H(II) - H(III) and H(II) - H(V), moderate correlation).

From Fig. 2 it follows that in general the number of days with hail in Georgia for averaging intervals of 20-30 years tends to decrease. So, in 2001-2021 compared to 1941-1960 the average number of days with hail per meteorological station decreased as follows: H(I) from 1.0 to 0.4, H(II) from 1.7 to 0.9, H(III) from 1.9 to 0.9, H(IV) from 2.0 to 0.5, H(V) from 5.2 to 2.1, H(I-V) from 2.4 to 1.0. In 1991-2021 compared to 1941-1970 the average number of days with hail per meteorological station decreased as follows: H(I) from 0.9 to 0.3, H(II) from 1.7 to 0.8, H(III) from

2.0 to 0.7, H(IV) from 2.0 to 0.5, H(V) from 4.7 to 1.7, H(I-V) from 2.3 to 0.8.

	H(I)	H(II)	H(III)	H(IV)	H(V)	H(I-V)
1941-1950	0.9	1.4	1.6	1.8	5.9	2.4
1951-1960	1.0	1.9	2.3	2.3	4.5	2.4
1961-1970	0.9	1.7	2.1	1.9	3.7	2.1
1971-1980	1.0	1.1	1.1	1.3	3.4	1.6
1981-1990	0.4	1.0	0.9	1.2	2.4	1.2
1991-2000	0.2	0.4	0.2	0.7	0.8	0.5
2001-2010	0.2	0.8	0.8	1.0	1.4	0.8
2011-2021	0.5	1.1	1.1	0.0	2.7	1.1

Figure 3: *Variability of the mean decade number of days with hail per meteorological station in the warm half of the year for climatic zones in Georgia in 1941-2021.*

The variability of the average ten-decade number of days with hail per weather station is as follows (Fig. 3): H(I) - weak variability from 0.9 to 1.0 in 1941-1980, a sharp decrease from 0.4 to 0.2 in 1981-2010, an increase to 0.5 in 2011-2021 ; H(II) - increase from 1.4 to 1.9 in 1941-1960, constant decrease from 1.7 to 0.4 in 1961-2000, increase from 0.8 to 1.1 in 2001-2021; H(III) - dynamics similar to the previous zone, growth from 1.6 to 2.3 in 1941-1960, constant decrease from 2.1 to 0.2 in 1961-2000, growth from 0.8 to 1.1 in 2001-2021; H(IV) - increase from 1.8 to 2.3 in 1941-1960, decrease from 1.9 to 0.7 in 1991-2000, increase to 1.0 in 2001-2010, decrease to 0 in 2011-2021; H(V) - continuous decrease from 5.9 to 0.8 in 1941-2000, increase from 1.4 to 2.7 in 2001-2021; H(I-V) - unchanged in 1941-1960 (according to 2.4), constant decrease from 2.1 to 0.5 in 1961-2000, increase from 0.8 to 1.1 in 2001-2021.

Trend of the mean number of days with hail per meteorological station in the warm half of the year for all climatic zones in Georgia in 1941-2021 is quite satisfactorily described by a fourth order polynomial (Table 3, Fig. 4).

Table 3. *Coefficients of the regression equation for the trend of the mean number of days with hail per meteorological station in the warm half of the year for climatic zones in Georgia in 1941-2021.*

$\alpha(R^2) < 0.005;\ 0.01 < \alpha(K_{DW}) < 0.05$

$H = a \cdot X^4 + b \cdot X^3 + c \cdot X^2 + d \cdot X + e$, *X – number of years, 1-1941….81-2021*

2001-2010	0.03	0.20	0.36	-0.21	0.33	0.14
2011-2021	0.50	0.35	0.67	-0.82	2.09	0.57

Figure 5: *Mean per decade rate of change of the mean number of days with hail per meteorological station in the warm half of the year for climatic zones in Georgia in 1941-2021.*

The variability of average per decade rate of change of the mean number of days with hail per meteorological station is as follows (Fig. 5): H(I)' - from -0.25 in 1981-1990 to 0.50 in 2011-2021; H(II)' - from -0.40 in 1971-1980 to 0.59 in 1941-1950; H(III)' – from -0.66 in 1971-1980 to 1.14 in 1941-1950; H(IV)' – from -0.46 in 1961-1970 and 1971-1980 to 0.84 in 1941-1950; H(V)' - from -1.48 in 1941-1950 to 2.09 in 2011-2021; H(I-V)' – from -0.51 in 1971-1980 to 0.57 in 2011-2021.

IV. Discussion

In Georgia, as one of the most hail-prone countries in the world, many studies have been devoted to the study of hail processes, the basis of which is hail climatology. In 2023, a systematic catalog of five types of natural disasters in Georgia was created (landslides, mudflows, hurricane winds, floods and hail) [14]. From this catalog, data on the number of days with hail in the warm half of the year (April-October) was selected for 22 weather stations in Georgia from 1941 to 2021.

Our early studies used long-term continuous data (1941-1990) on number of hail days at 123 weather stations [3]. Accordingly, statistical characteristics were studied in detail, including the variability in the number of days with hail for 15 climatic zones of Georgia over the specified 50-year period of time. After 1990, the number of weather stations decreased significantly, and we proposed a different approach to studying long-term variations in the number of days with hail. Namely, an analysis of the variability of the number of days with hail averaged per meteorological station for five climatic zones, which includes four climatic groups according to the Köppen classification. In our opinion, this approach is promising and will be developed by us in the future.

V. Conclusion

In the future, it is planned to study in more detail time series of number of days with hail averaged per one meteorological station for indicated above 5 climatic zones (autocorrelation analysis, periodicity, etc.), as well as to conduct an interval forecast of the number of days with hail, taking into account periodicity, etc.

Abstract

Landslide processes are typical for the territory of the Chechen Republic. Loose deluvial material on the slopes created favorable conditions for the development of fertile soils and mountain agriculture in the main areas of residence of Chechens in the low-mountain and mid-mountain parts of the region. Population growth and the use of new technologies for land cultivation, irrigation, road construction - all this led to an increase in the load on the slopes and, as a consequence, to the activation of landslide activity. Mass destruction of houses and roads, often accompanied by human casualties, led to an outflow of population from the mountains to the plain, planned resettlements from areas of increased landslide danger. All this could have become one of the factors increasing social tension in the region in the late 1980s. Currently, the problem of reducing the risks of landslide danger in the region has not been solved, although there are detailed studies. The purpose of this work is to develop a comprehensive geoecological approach to landslide mapping using the landscape concept. To achieve this goal, two levels of mapping detail were used: 1) mesoscale mapping of landslides in the mountainous part of the territory of the Chechen Republic; 2) large-scale mapping in a key area in the low-mountain zone.

Keywords: landscape-landslide areas, relief, slope exposure

I. Introduction

Landslide processes are widespread in the mountains and are the result of a complex combination of exogenous and endogenous processes, which are also affected by economic activity. The study of landslides is relevant due to the increased risks associated with the implementation of projects for the recreational development of mountains, road construction, and communication lines. For a long time, the study of landslide processes was the prerogative of industry specialists, mainly engineering geologists and geomorphologists. The development of this field has attracted specialists studying not only geology and relief, but also vegetation, climate, and socio-economic processes in areas with landslide processes. Currently, landslide mapping cannot be done without reflecting on the maps the connections between natural components (relief, lithology, climate, vegetation), on the one hand, and natural and anthropogenic ones, on the other. This formulation of problems fits into the integrated direction of studying mountainous areas. The development of an integrated geoecological direction of landslide mapping is facilitated by modern methods of geoinformation mapping using high-resolution remote sensing materials obtained at certain intervals [3,9].

II. Methods

The work is based on field research materials combined with image interpretation. Landslide identification was based on images provided by the Google Earth service. It was a detailed analysis of images from different years together with field surveys that formed the basis for creating the database. The algorithm for identifying and analyzing landslide dynamics includes a detailed review of the territory of the Chechen Republic using images of different scales, plotting the identified landslide processes on maps in the GIS environment, verifying the established landslide areas using images from different years, and field surveys to establish the nature of landslide dynamics. As a result, about 2,400 landslide areas were identified, and after clarification and generalization, 1,800 landslides in the Chechen Republic were entered into the database. At the regional level, landslide mapping was based on establishing the locations of landslide manifestations, their confinement to slopes of different exposures and inclinations, as well as to certain landscapes. For this purpose, slope and aspect maps obtained using geoinformation modeling were used, as well as a landscape map created earlier in the field [4,12].

For a more detailed assessment of the complex of natural and natural-anthropogenic connections underlying landslide manifestations, landscape mapping of a typical landslide in the low-mountain zone of the Chechen Republic was carried out. For this purpose, a combination of field and office interpretation of large-scale photographs of different years was used, with the allocation of landscape contours and elements of the landslide body.

Landslide mapping varies in industry and complex scientific fields. The study of landslide phenomena has long been the prerogative of geologists and geomorphologists. There are more than 140 definitions of landslides in the literature, most of which are based on geological and geomorphological classification features. Over the past decades, many fundamental works have been published that consider landslides as geological bodies and complex slope processes [6]. As a rule, a classic landslide map included graphic tools and symbols that showed the geological and geomorphological features of the landslide: a breakaway wall, a pressure shaft, boundaries and composition of rocks, groundwater, etc. Much attention was paid to profiling in order to show the angles of inclination and bends, the relationship of geological rocks in the structure of landslides. In rare cases, information about vegetation was used as additional designations. Landslide mapping from a geoecological perspective shifts the focus to the entire host landscape, and the mapping is based not on the landslide bodies themselves, but on the so-called landscape-landslide complexes. A comprehensive study of landslide phenomena within the landscape concept takes into account the hierarchical structure of natural differentiation, which implies that in addition to studying individual landslide bodies, it is necessary to study the structure of natural complexes from local to regional levels of landscape differentiation. At the regional level, the study of landslides implies taking into account the altitudinal-zonal structure of landscapes. At the local level, mapping aims to reflect landscape-landslide complexes: in addition to the landslide body, mapping includes elements of the landscape structure and land use.

III. Results

The mountainous part of the Chechen Republic is characterized by a complex relief, the predominance of sedimentary rocks of different ages (from Neogene-Paleogene deposits in the foothills to Cretaceous and Jurassic in the foothills and highlands), subject to exogenous processes. The orographic features of the ridges and the composition of the sedimentary rocks that compose them, metamorphosed to one degree or another, reflect a consistent transition from low-mountain ridges to mid-mountain and mid-mountain basins (Rocky ridge) up to the highlands of the Lateral ridge.

Layer-by-layer visualization, with an emphasis on a particular relief characteristic, makes it possible to approach the analysis of landslide distribution from different angles. The maximum height of landslides identified in the Chechen Republic reaches 2700-2800 meters on the northern slopes of the Snow ridge (on the border with Dagestan). As will be shown below, these territories and landscapes are characterized by severe degradation of the soil and vegetation cover as a result of long-term grazing. The lowest absolute heights (about 100 m), to which landslides are confined, are typical for the slopes of the Gudermes Ridge. Here, landslide stimulation is associated with oil production areas. Most landslides are confined to the altitude step from 500 to 600 meters (193 landslides). The second maximum (146 landslides) gravitates towards heights of 1700-1800 meters.

Above 2000 meters, the number of landslides drops sharply due to worsening conditions for landslide formation: rocky slopes and a decrease in the thickness of the loose cover, a decrease in anthropogenic activity, etc. The slope of the surface determines the potential energy of the relief and the intensity of the processes of exogenous geodynamics, including landslides of various types. Slopes also increase from north to south along with the growth of absolute height.

The ratio of the areas of slopes of northern and southern exposures is approximately the same due to the sublatitudinal bends of river valleys and the extension of ridges. The distribution of landslides is also approximately the same, which indicates a weak influence of slope exposure on landslide formation processes; landslides are formed almost equally on slopes of different exposures, although there are some deviations [2,10].

As can be seen from figures 1 and 2, the greatest number of landslides (55%) are confined to slopes of warm exposures (southern, southwestern and southeastern). Although in terms of area, slopes of northern orientation prevail in the region, related to the northern slope of the ridges of the North Caucasus. All this emphasizes the complex nature of the confinement of landslides to slopes of various exposures and different steepness. The revealed regularities can be explained by the following hypotheses: 1) the slopes of southern exposures are less forested, and therefore less resistant to landslide formation; 2) the slopes of southern exposures were more developed, which means that the soil and vegetation cover was changed here, which could also lead to instability of the slopes to landslide formation. The combination of the terrain height, slope inclination and slope exposition generally provides the set of conditions that are inherent in landslide formation. Slope inclination, height and slope exposition are three variables, the combination of which allows us to assess the nature of the combination of factors and highlight the role of each of them in landslide formation. Exposition differences do not play a large role in the confinement of landslides to small angles of inclination (up to 150). This is generally consistent with the known geoecological regularities: the differentiating role of exposition is weak for slopes of small steepness. With increasing steepness, the role of "warm" exposures increases, where most landslides occur. The differentiation of landslide distribution by exposure is most noticeable in the altitude range of 500-2000 meters. Here, the difference in the intensity of landslides on the slopes of southern (frequently) and northern (comparatively less) exposures is especially noticeable. With increasing absolute altitude (more than 2000 meters above sea level), this pattern does not manifest itself [7,11].

Landslides in mid-mountain and low-mountain forest landscapes are a special phenomenon. Such landslides often occur in old forests far from settlements. A number of landslides can only be detected from photographs; there are no roads or paths to them, and they can only be reached along river beds. The most striking example of landslide manifestation in mountain-forest landscapes, transitional from mixed to broad-leaved, is a landslide near the Sharoargun river opposite the village of Ulus-Kert. The study area is characterized by the development of landslides, the formation and development of which are caused by the impact of mainly regional factors, such as the clay composition of rocks, physicochemical and deformational features of rocks, which determine their ability to quickly loosen and soften, neotectonic movements, bottom and lateral erosion, seismicity and hydrometeorological factors [1,5]. The scheme of the Ulus-Kert landscape-landslide complex reflects the main features of the integration into the altitudinal-zonal structure and the relationship with the dominant background natural complexes at the level of groups and types of landscapes. The landscape-landslide complex in plan has several longitudinal parts with different ages of landslide activation (Fig. 1,2). The upper wall of the breakaway is at an absolute height of about 770 m above sea level, and the discharge ends in the river bed at an altitude of 410 m. There are several classic landslide elements characteristic of a block landslide: 1 - landslide block; 2 - landslide terrace area; 3 - landslide failure wall; 4 - landslide pressure shaft ending in the river.

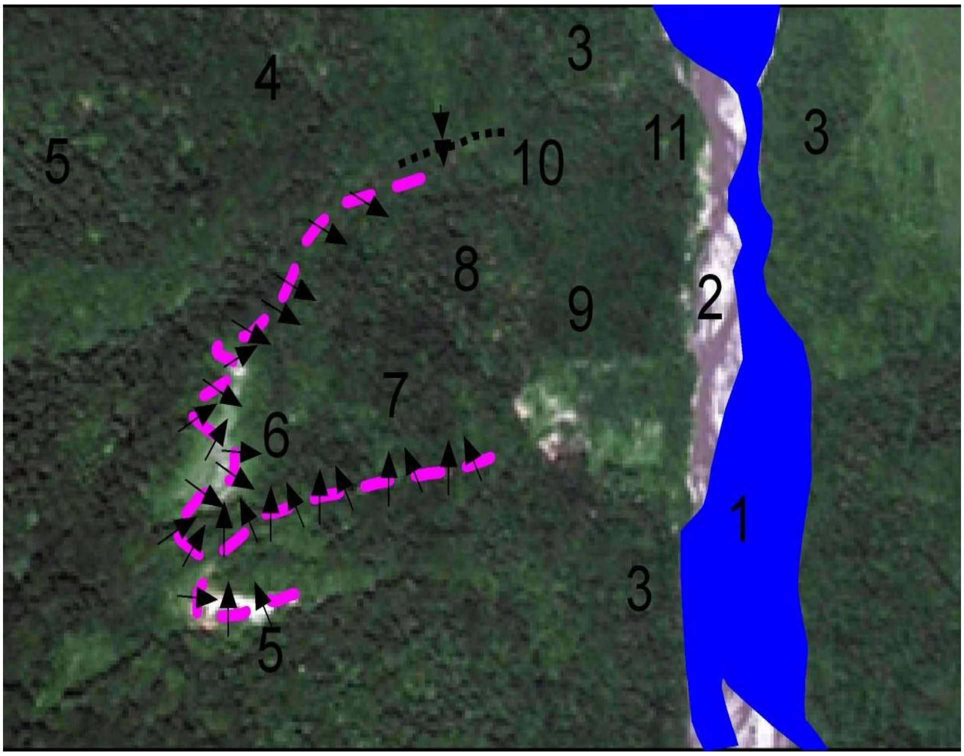

Figure 1: *Landslide in the bed of the Chanty-Argun River*

Legend: 1 - floodplain natural complexes (river bed), 2 - high floodplain overgrown with shrubs (about 10 years), 3 - slopes of river terraces under small forests of beech, hornbeam, hawthorn, maple; 4 - under hornbeam-beech forests with undergrowth of hawthorn and maple on mountain brown soils, 5 - beech forests on mountain brown soils, 6 - landslide failure wall, not sodded; 7 - area of the upper landslide terrace with clumps of beech undergrowth, less often hornbeam and hazel; 8 - section of the slope of settling, hummocky-ridged under the "drunken" forest of beech, hornbeam on pocket and skeletal brown soils, 9 - the site of the lower landslide terrace under blackberry thickets and willow clumps, 10 - lateral depressions of settling under beech forests, 11 - pressure landslide rampart under willow thickets with alder.

Analysis of landscape embeddedness shows that landslide formation sharply contrasts with mountain-forest landscapes, characterized by a relatively stable state of slopes. Landslide foci in this case are not typical for local geosystems. Rather, they characterize a certain shift in the regional ecobalance.

For a more comprehensive understanding of the landslide phenomenon, considering it as a landscape-landslide complex, it is necessary to take into account its embeddedness in the landscape structure (Fig. 3). [4,10]. Embeddedness in the landscape structure of the Kert landscape-landslide complex is characterized by the following features:

1) at the level of landscape types - a weakly contrasting ecotone position between the mountain-forest and mountain-forest-meadow-steppe zone, as well as between mountain-forest broad-leaved and mountain-forest mixed landscapes;

2) at the level of landscape groups: the borderline position between rocks with different proportions of clays and sandstones of Paleogene-Neogene age is weakly expressed. A more important factor is the location in the zone of tectonic faults and seismic dislocations;

3) at the level of landscape types - fragmentation of forest cover due to successional

differences in forests of different ages and phytomass reserves. The dynamics of landslides may seem quite simple: the deepening river bed washes away the right side and leads to instability of the slopes. However, field studies have shown that other factors may also play a role in the dynamics of landslides: increased seismicity, contrast of rocks forming the slope, succession processes in forests leading to an increase in above-ground phytomass with a decrease in sod cover in dead-cover beech forests, leading to the development of erosion centers, torrential precipitation at the beginning of summer, leading to instability of soils to erosion, etc. [9].

Figure 2: *Landslides Manifestation in the bed of the Chanty-Argun River (from the side of the village of Kert*

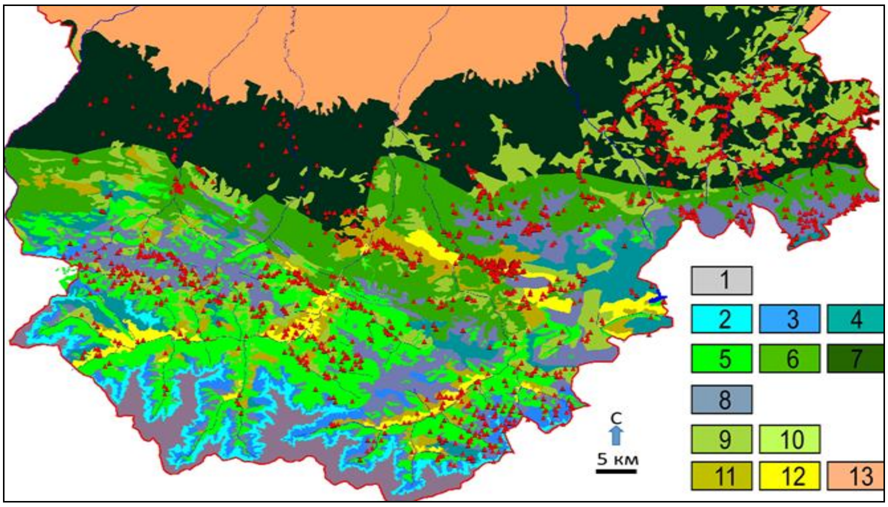

Figure 3: *Mapping of landslide areas in the mountainous part of the Chechen Republic*

Landscape differentiation at the level of landscape groups is determined by differences in rock types and relief. As can be seen from the map of landslide distribution by landscapes, the altitudinal-zonal distribution of landslides is discrete and uneven: areas of landslide concentration alternate with areas where they are practically absent.

IV. Discussion

An analysis of landslide distribution in the mountainous part of the Chechen Republic showed that the maximum height of the identified landslides reaches 2700-2800 meters on the northern slopes of the snow Ridge. The lowest absolute heights (about 100 m), to which landslides are confined, are observed on the slopes of the Gudermes ridge, which is associated with oil production. Most landslides (out of 1800 identified) are confined to the altitude interval from 500 to 600 meters (193 landslides). The second maximum (146 landslides) is confined to heights of 1700-1800 meters. The largest number of landslides is confined to slopes with a steepness of 25-350. The number of landslides on steep slopes (more than 350) decreases, but still remains relatively large. The largest number of landslides (55%) are confined to slopes with warm exposures (southern, southwestern and southeastern). This is due to the deforestation of the southern slopes and anthropogenic activity. Large-scale mapping of the landslide made it possible to identify the main elements of the landscape structure, which are at different stages of vegetation succession and experience different anthropogenic loads. The ecotone position between two types of landscapes (mountain-forest and mountain-forest-meadow-steppe) plays an important role in the dynamics of the Belgatoy landscape-landslide complex [8]. The dynamics of landslide processes in this area are largely due to the fragmentation of forest natural complexes due to selective deforestation, construction of plowed terraces and serpentine roads. Landscape-geomorphological large-scale profiling and mapping of specific landslide areas and landslides using GPS and GIS technologies (primarily, superimposing layers of geology, quaternary deposits, vegetation on a digital elevation model is an effective method for analyzing landslide mechanisms in specific natural and economic conditions. GIS modeling allows us to establish a number of patterns in the distribution of landslides. However, formal tools of morphometric analysis cannot fully explain the distribution of landslides and their nature. Field data are needed for this.

Abstract

The article considers the theoretical and methodological basis associated with the study of problems in the field of increasing the efficiency of using alternative energy supply options for production. The potential of alternative energy and the possibility of its use in the energy supply of production has been investigated and evaluated. A mechanism for analyzing the use of alternative options in the energy supply of production has been developed. The reserve possibilities associated with the use of alternative energy sources have been studied. A model for evaluating the efficiency of using alternative energy sources is proposed. A mechanism has been developed to increase the efficiency of using alternative energy supply options for production.

Keywords: efficiency, alternative energy supply options, expenses, energy sources, cost, investment

I. Introduction

Nowadays, factors such as rapid development of industry and agriculture along with the increase in the number of people and the rising standard of living of the people, sharp increase in the number of energy-usage in households, increase of the demand for organic and inorganic fuels day by day proves to be challenging, and leaves us crossroads to face the global environmental problems, and to search for the application of new, ecologically clean energy sources, is causing scientists to think more often on the above matter.

Over time, it is inevitable that the countries of the world will face the exhaustion of non-renewable energy sources - oil, gas and coal. In addition to depletion of these sources, it is also observed that they are becoming more expensive. Also, the negative impact of traditional energy exploitation, burning and other factors on the ecological situation of our planet is becoming more and more evident. To prove the usefullnes of the transition, since the use of renewable energies as alternative energy sources is more ecologically efficient, it is necessary to investigate their sources, ways of using them, their effects on nature, and many more issues as they have become very relevant in the current period. Wind, solar, wave and hydrological energy of small rivers are just such sources and their potential possibilities are limitless and inexhaustible. What we mentioned above reflects the relevance of the topic [3].

II. Methods

The economic indicators of using alternative energy sources are somewhat more expensive than the economic indicators of using traditional energy sources. Turkish scientist Muhammet Kayfeci has investigated some of the renewable energy sources in detail. The first area observed in this regard will be solar energy. Solar energy is radiant energy produced by the conversion of hydrogen into helium at high pressure and heat in the core of the sun. The amount of energy generated by the sun in 1 second is more than the amount of energy used by society. The world receives only one billionth of the energy from the sun. The volume of solar rays entering the earth's surface is 0-1100 W/m2. According to the researches of Muhammet Kayfeci, we can concentrate the application of solar energy in 2 groups.

Group I – Conversion of heat obtained from solar energy into electrical energy

Group II – Direct conversion of solar energy into electrical energy

In the system belonging to group I, heat is first obtained from solar energy. In addition to using this heat energy directly, it can also be used in electricity production. In group II, solar rays are directly converted into electrical energy through systems mentioned as Photogalvanic. The most basic system investigated here in connection with our topic is the application of the system mentioned as solar panels or photovoltaic panels. These panels are semiconductor materials that directly convert sunlight falling on their surfaces into electrical energy. These panels are mostly square and round and have a surface area of about 100 cm2 and a thickness of 0.2-0.4 cm. When light falls on the surfaces of the panels, an electric voltage is generated at their ends. In this regard, the source of the electric energy provided by the panel is the solar energy falling on the surface. Many panels are placed parallel to each other to increase the volume of generated energy. The structure in this form is called a photovoltaic model. These models create systems that provide energy from several W to MW. The productivity of panels used for obtaining solar energy varies according to the type of materials used in production.

15%-17.5% in monocrystalline structures

12%-14% in polycrystalline structures

In siliceous structures, a productivity of 5%-8% is created. [5]

Associate Professor Sabahatdin Unalan divided the use of solar energy into 3 parts according to the limits of heat during his research:

- Low heat level (below 150°C) – used for salt production, heating of buildings, drying of crops in the farm.
- Medium heat level (150-600°C) – start small motors and generate electricity with steam generator
- High heat level (600 °C and more) – electricity production, creation of exotic substances, use of solar ovens.

Currently, the technical potential of wind energy in the world is calculated as 53,000 tWts/year. The most important parameter in calculating the amount of energy generated using wind power is wind speed. From this point of view, the amount of wind energy that can be produced is expressed in the following form:

$$P = \frac{1}{2}\rho A V^3 \tag{1}$$

P – amount of energy produced;

A – Rotor swept area;

ρ – air mass density;

V – air velocity.

Rick DeGunther, a graduate of Stanford University, considered the following alternative energy source in his research. The aim of these studies is to identify different renewable energy sources and discover the possibilities of their effective use.

Biomass, which is the main source of energy in many parts of the world, is the biological mass formed as a result of plants converting solar energy into chemical energy through photosynthesis. Biomass energy is the type of energy produced as a result of using biomass waste by burning it or going through different procedures. Biomass energy sources include 3 elements, which are part of the daily life of 1/3 of the world's population. They include natural products, animal manure, industrial and household waste. Turning waste into usable energy has very little negative impact on the environment.

Hydroelectric power - water in lakes, seas or rivers evaporates under the influence of the sun, and the resulting water vapor moves and falls on the slopes of mountains in the form of rain and snow, feeding water basins. Here, the production of energy consists of the energy generated during the movement of a large amount of water from a certain height to a lower level, using turbines to bring it into the form of mechanical energy.

There are 3 systems for using wave energy. A Shoreline system is a system fixed on the seashore, easy to maintain and does not require underwater electrical wiring. The OVC system is located under water, and as a result of the wave hitting the system, the water level rises, the air level is compressed, and the turbine rotates and electricity is produced. The pendular system is a cube-shaped system with one side facing the sea. The cover placed on it moves back and forth under the influence of the wave and produces electricity (2). Jenny Hayward and Peter Osman in their article "The potential of wave energy" suggested that wave energy is important and proposed 3 devices for its use. The point absorption device is located in the depths of the water and moves as a result of the pressure generated regardless of the direction of the wave movement and energy is produced. A device called linear absorption has large propellers relative to the height of the wave and rotates depending on the speed of the wave and produces energy. The device called Terminator works only due to the waves in the direction in which it is installed.

Determining the kWh costs resulting from the application of different technologies makes it possible to compare those technologies and determine which one is more efficient (5). The calculation of the cost of energy production is as follows:

$$C_e = [CI + (M \cdot CI \cdot V_u)] \div (P \cdot h \cdot V_u) \tag{2}$$

C_e-cost of energy production (USD/kW);
CI-initial cost of installation;
M-maintenance costs (annual interest on initial cost of installation);
V_u-the number of useful years that can be used;
P-installed power (kW);
h-annual usage hours [6].

Along with the positive aspects of alternative energy types, there are also negative aspects and they are reflected in Table 1.

Table 1: *Advantages and disadvantages of energy types*

Types of energy	Advantages	Disadvantages
Sun	It is an inexhaustible, abundant, cheap, non-dependent resource	The constant absence of sunlight, the lack of sunlight during the winter months and the absence of it at night
The wind	It is found freely in the atmosphere, its price does not increase over time, maintenance and use costs are low	The initial investment cost is very high, there is a mismatch between supply and demand, and it is noisy
Geothermal	Productivity is more than 95%, lack of meteorological dependence, minimum area requirement	Lack of portability, cannot be produced everywhere
Hydroelectricity	No waste during production, high productivity, cheap energy production	The cost of creating a HPP is high, it affects the climate where it exists, and it affects animals and plants.
Biomass	The possibility of storage, the possibility of using everywhere, not causing acid rain	Release of methane gas that can affect the ozone layer, high demand for water.
Wave	It is infinite, has no impact on the environment, the possibility of turning salt water into fresh water	A system must be built for each wave height, it is noisy, and maintenance costs are expensive.

Another criterion is the evaluation of the investment in the field of alternative energy, where there are 3 methods.

Payback period – It is used to calculate how many years the initial investment will be returned

Net Present Value (NPV) - if the present value of the amount of money received in the future is greater than the amount of the initial investment, the project will be implemented.

$$NPV = \sum_{t=1}^{n} \frac{CF_t}{(1+r)^t} - \dot{I} \quad (3)$$

CF_t- cash flow at the end of year t

İ- initial investment

r- discount rate/required rate of return on investment

n- duration of the project

Internal rate of return (IRR) is an indicator of the net cost for the project equal to zero. It covers the situation where the costs are equal to the future cash flows.

III. Results

Thus, the following are the conclusions and suggestions we have obtained thanks to our research:

1) The development of the alternative energy market will create conditions for the formation of the need for specialized personnel not only in this field, but also in repair, assembly, logistics and sales - new jobs will be opened.

2) An entrepreneur who applies renewable energy systems will not incur additional costs for obtaining energy from the state and will make a profit as a result.

3) In order to increase the efficiency of using solar energy in the production process, the use of PV panels, the panels should be placed at an inclination angle of 25°, and in order to minimize the amortization period, which has the ability to pay 80% of the consumer demand, including the number of sunny and windy hours in our country. However, I suggest the establishment of systems in this field, the implementation of transfers by the state to entrepreneurs, and the creation of photovoltaic systems with monocrystalline structure from wave and hydroelectric power in regions with abundant water bodies, as well in the places where industrial enterprises are located.

IV. Discussion

I. Study of backup possibilities related to the use of alternative energy sources.

Below is the trend of the cost of production of 1 kWh of energy between (2014 –2022).

According to the forecasts of the International Renewable Energy Agency, it is estimated that by 2025, the costs incurred for the production of 1 kWh of energy will decrease by 30-50%. Also, it is thought that the investment volume for 1 kW will decrease from the level of 5000-6000 US Dollars to the level of 3500-4000 US Dollars.

Naturally, the decrease in investment and production costs will lead to the establishment of new systems in this field and the opening of new jobs. In particular, the development of the alternative energy market will create conditions for the formation of the need for specialized personnel not only in this field, but also in repair, assembly, logistics and sales. The International Renewable Energy Agency reports that 10 million people are currently working in this field. In the last 4 years, the number of workers working in the fields of solar and other energy production has doubled, and it is planned that 24 million people will be employed by 2030. The distribution of employees by fields is as follows [2]

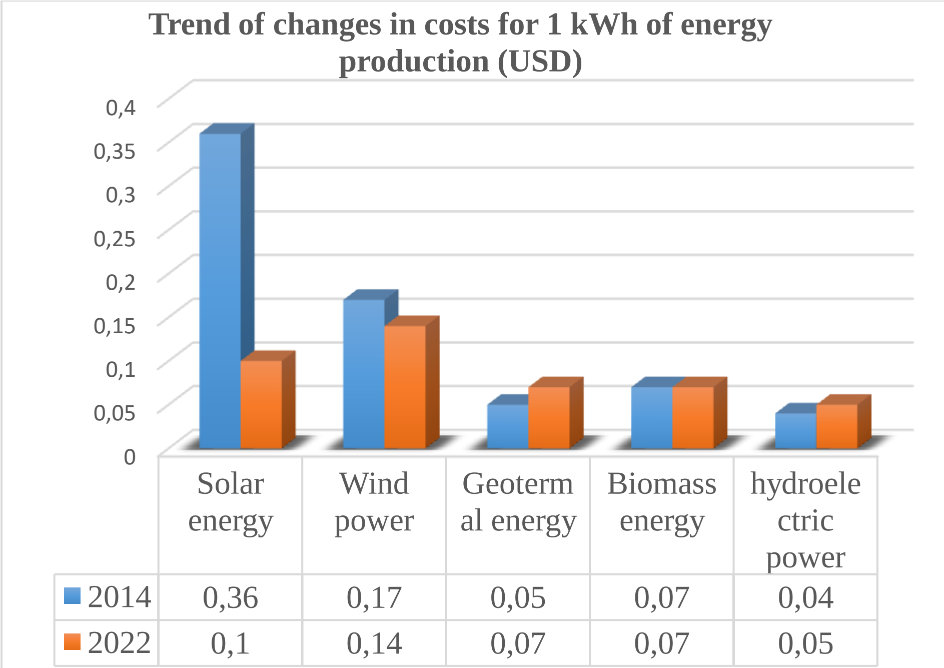

Figure 1: *The trend of change in the costs incurred for the production of 1 kWh of energy provided by the IRENA organization.*

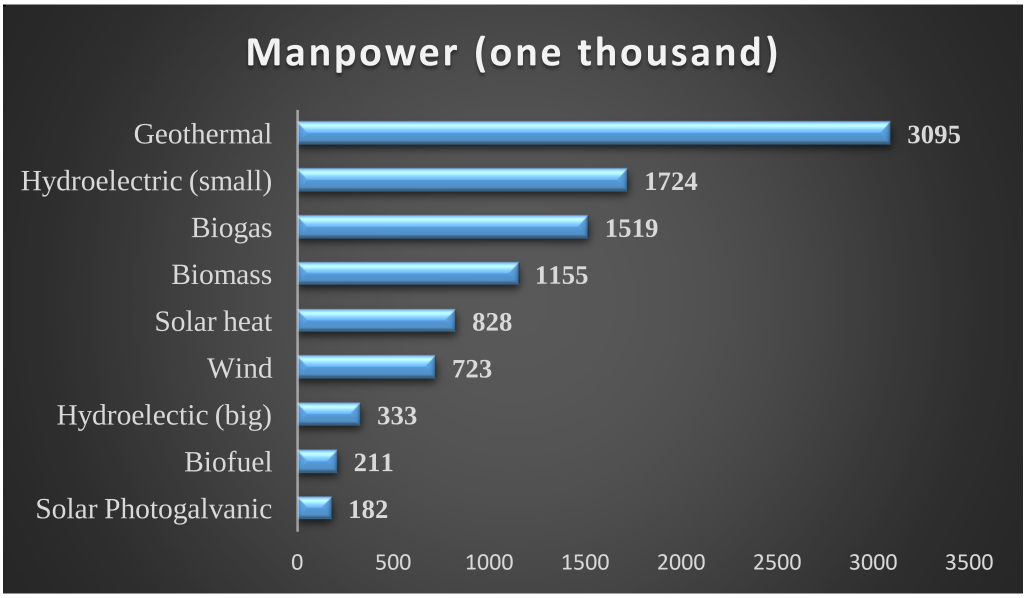

Figure 2: *Number of employees working in the field of alternative energy*

II. The efficiency of using alternative energy sources evaluation model

As a result of our research, we have identified a number of positive and negative aspects of renewable energy sources. Currently, the most widely used solar energy systems around the world have a certain economic benefit, both economically and environmentally. First of all, let's note that photovoltaic panels used for obtaining solar energy are monocrystalline, polycrystalline and thin-layer silicon crystals. [4] To determine the efficiency that those panels give us, the calculation of the hourly ray coming to the horizontal surface is initially calculated by the formula (4):

$$\dot{I}_{TE,s} = \dot{I}_{be,s} + \dot{I}_{de,s} + \dot{I}_{re,s} \tag{4}$$

In this calculation, the hourly solar radiation arriving at the horizontal surface $İ_{TE,s}$ (kVth/m2)), direct (or direct) rays falling on the surface $İ_{be,s}$ (kVth/m2), scattered rays $İ_{de,s}$ (kVth/m2) and $İ_{re,s}$ (kVth/m2) are defined as the sum of reflected rays. In Liu and Jordan's model, the calculation of direct (or direct) solar radiation falling on the surface is determined by the formula (5):

$$İ_{be,s} = İ_{b,s} R_b \quad (5)$$

Here $İ_{b,s}$ (kVth/m2)is the hourly amount of direct rays falling on the horizontal surface, and , R_b is the energy conversion factor of that ray.

Calculations on electricity production based on the sun's rays falling on the earth's surface have been carried out. As a result of these calculations, the total collector area $A_k(m^2)$, hourly electricity production $E_s(kWts)$ (6), daily electricity production $E_{gün,n}(kWts)$ (7), monthly electricity production $E_{ay,i}(kWts)$ (8) and annual electricity production $E_i(kVts)$ are given in equations (9)

$$E_s = İ_{TE,s} * A_k * \eta^* \quad (6)$$

$$E_{g,n} = \sum_{s=5:00}^{19:00} E_s \quad (7)$$

$$E_{a,i} = \sum_{n=1}^{y} E_{gün,n} \quad (8)$$

$$E_i = \sum_{i=1}^{12} E_{ay,i} \quad (9)$$

Here, the s-index indicates the time at which the calculations are made, the n-index indicates the number of days in a year, the i-index indicates the month in which the calculations are made, and the y-index indicates the number of days in a month η* the electricity production of the panel due to the heat from the sun [8]

In our article above, we mentioned that the use of solar energy systems has both economic and environmental benefits. First, let's consider its environmental efficiency and do the math. As we know, a certain amount of CO2 emissions are released into the environment during the production of heat or electricity using traditional fuels.

Solar photovoltaic systems are used to reduce this and for a healthier environment. As a result of the application of those systems, the amount of CO2 emission avoided in general was calculated in the equation $T_{avoided - CO_2}$ (kg CO_2) (10), the produced emission factor $n_{CO_2}(\frac{kgCO_2}{kwts})$. The produced emission factor is given below (Table 2), and the product of the annual energy production volume and the production rate of the corresponding fossil fuel indicates how much CO_2 emissions are prevented.

During the production of photovoltaic panels, the average emission factor is 3,301$(\frac{kgCO_2}{kwts})$ and is negligible and is marked as n_{PV-CO_2}.

The emission factor $T_{PV-CO_2}(kgCO_2)$ (11), the amount of avoided CO_2 T_{CO_2} $(kgCO_2)$ during the construction of those systems is (12) is shown in the equation, and the power of the overall built photovoltaic system is expressed as $P_g(kWt)$.

Table 2: *Produced emission factor*

Fuel type	Emission factor $(\frac{kgCO_2}{kwts})$
Natural gas	0.201
Oil	0.266
Brown coal	0.327-0.414
Stone coal	0.322-0.358

$$T_{avoided-CO_2} = E_{il} * n_{CO_2} \quad (10)$$

$$T_{PV-CO_2} = n_{PV-CO_2} * P_g \quad (11)$$

$$T_{CO_2} = T_{avoided-CO_2} - T_{PV-CO_2} \quad (12)$$

The next efficiency we will consider is economic. The first area to be calculated is depreciation. Depreciation is denoted by t (year), in equation (13) the initial construction cost G (dollars), the total PV cost G_{PV}, the land cost G_{land} for the creation of solar energy systems is calculated in proportion to the total profit level.

$$t = \frac{G + \text{Gland} + G_{PV}}{K_{top}} \tag{13}$$

The monthly, total, LEIQ, and total local product profit to be obtained during the construction of photovoltaic systems are expressed by formulas (14), (15), (16), (17), respectively. Before moving on to the calculations, it should be noted that wholesale electricity prices $F_{k-1,i}$ is a variable parameter, so different results are always obtained. When calculating the profit to be obtained, the increase in electricity prices is assumed to be approximately 10%. In this regard, the "m" coefficient, which takes into account the increase, was mentioned in the calculation 3.11 regarding the electricity price.

$$F_{k,i} = F_{k-1,i} * (1 + m) \tag{14}$$

$$F_{i-ort} = \frac{\sum_{k=1}^{z} F_{k,i}}{z} \tag{15}$$

$$K_{ay,i} = E_{ay,i} * F_{i-ort} \tag{16}$$

$$K_i = \sum_{i=1}^{12} K_{ay,i} \tag{17}$$

In the formula (14), the electricity sales price for any month is calculated with $F_{k-1,i}$. In the above formulas, the k-index is the number of years, the z-index is for determining the estimated depreciation period as a year, and the i-index is the number of months. As a result of the calculation by formula (15), the annual average electricity price is determined according to the estimated amortization period for each month. [7]

According to the law of unlicensed electricity production, the amount paid by the state for each kilowatt of energy produced with alternative energy and sold to the grid $F_{LE\dot{I}Q}$significantly positively affects the amortization period in economic and technical matters. If the total LEIQ profit is K_{t-leiq}, the electricity consumption according to the consumption demand is shown as $E_c(kVts)$, the total profit from the LEIQ is calculated as follows:

$$K_{t-leiq} = F_{leiq} * (E_i - E_c) \tag{18}$$

PV panels, which provide the production of electricity from solar power plants to the grid, provide state subsidies for each kW if they are produced locally. If we express that paid aid as F_{local}, then the total local profit obtained will be as follows.

$$K_{t-leiq} = F_{local} * (E_i - E_c) \tag{19}$$

As a result of this final calculation, the total efficiency or gain obtained from the use of GES is equal to the sum of the gain obtained from the use of LEIQ, the use of domestically produced PV, and the prevention of the emission factor that jumps into the environment.

$$K_t = K_{t-leiq} + K_{t-leiq} + K_i + K_{CO_2} \tag{20}$$

$t = (G + +G_{PV})/[(F_{local} * (\sum_{i=1}^{12} \sum_{n=1}^{y} \sum_{s=5:00}^{19:00} \mathrm{I}_{TE,s} * A_k * \eta^*)) + (F_{leiq} * \sum_{i=1}^{12} \sum_{n=1}^{y} \sum_{s=5:00}^{19:00} \mathrm{I}_{TE,s} * A_k *$
η∗))+i=112(i=112n=1ys=5:0019:00ITE,s∗Ak∗η∗∗k=1zFk−1,i∗1+mz+i=112n=1ys=5:0019:00IT E,s∗Ak∗η∗∗nCO2−nPV−CO2∗Pg∗FCO2] (21)

$\eta^* = \mathrm{I}_{TE,s}/(\frac{12*3600}{\pi} G_{sc}(1 + 0.033 \cos\frac{360n}{365})*[\cos\varphi \cos\delta\,(\sin\omega_2 - \sin\omega_1) + \frac{\pi(\omega_2-\omega_1)}{180} \sin\varphi \sin\delta]) * (\eta_r -$
$\mu((T_a + (PN\c{C}\dot{I} - 25^{\circ}C)\frac{I_{TE,s}}{1000}) - T_r))$ (22)

G_{sc} − constant sunlight
PNÇİ – Normal operating temperature of the panel($^{\circ}C$)
η_r − performance indicators of the PV system during the test (%)
T_r − The temperature at which the PV system is tested

$\mu -$ Thermal coefficient of PV system

As a result of the calculations, it was determined that if the average monthly solar energy falling on 1 m^2 of surface is 120-130 kW, then the photovoltaic system used in the GES with a total power of 100 kW is placed at an angle of inclination of 30° and the productivity is 14-15%, and it produces approximately 70,000 kW annually. produces electricity (22). In this case, the amortization period of that PV system is determined to be 10 years (21). The entrepreneur who built this system would have made a profit of approximately 17,000 dollars because he did not buy 70,000 kW of electricity from the state grid. Also, with the construction of this system, 13,873 kg of CO_2 emission factor is prevented from being thrown into the environment. [1]

There are two computer simulations used in this area. One is called RetScreen and the other is called Enhanced simulation. Both simulations were used for systems with a power of 100 mW in areas with 1200-1800 kW of solar energy per 1 m^2 of horizontal surface annually, and the results are listed in Table 3.

The reasons for the differences resulting from the use of both simulations are that the developed simulation, unlike RetScreen, takes into account the increase in the price of electricity production, the amount of CO_2 produced by PV production, the land costs related to the construction of PV systems, and other parameters. The use of this simulation is considered to be more effective because the developed simulation provides conditions for obtaining more extensive, detailed and reliable results.

Table 3: *The results of the simulations used*

Parameter	RetScreen	Advanced simulation	Offset (%)
$E_i(kWts)$	142.000	144.572	-1.8
$T_{CO_2}(ton)$	28.5	29	-1.8
$t(i)$	7.2	7.0	2.7

As we mentioned above, there are monocrystalline, polycrystalline and thin-layer silicon crystal types of photovoltaic systems. Their efficiency differs from each other. Let's consider which one is more efficient:

1) When we use thin-film silicon crystal PV panels, to build a system with 1000 panels with a power of 100 kW, it will cost approximately \$85,000, additional installation costs of \$97,000, and land costs of \$68,950, for a total cost of \$250,950. happens. Since the prices of thin-film silicon crystal PV panels are more expensive than polycrystalline panels, it causes us to invest an additional \$19,000. At this time, we can produce 45,000 kilowatts of electricity annually. A total profit of \$18,000 is obtained during the application of a thin-film silicon crystal PV system, the amortization period is 14 years, and the amount of CO2 emissions avoided is 8,000-9,000 kg.

2) When monocrystalline PV panels are used, the total cost under the same requirements is \$245,000. However, due to the high productivity of this type of PV panels, the volume of electricity production has changed and increased compared to polycrystalline panels. As a result of the application of such a system, more than 72,000 kilowatts of electricity is produced annually and \$22,000 in profit is obtained. The amortization period is reduced to 11 years, and a total of 14,000 kg of CO2 emissions are prevented.

3) As a result of research on polycrystalline PV panels, it was determined that the amortization period is 9-10 years and it has the ability to satisfy more than 80% of the proposed demand.

Table 5: *Amortization periods that occur as a result of changes in inclination angles in the conditions of meeting consumer demand*

$E_i(kWts)$	Lack of government support for CO_2 mitigation and the use of locally produced PV panels						Availability of government support for CO_2 mitigation and use of locally produced PV panels					
Angles of inclination	20	25	30	35	40	45	20	25	30	35	40	45
186.000	8.60	8.58	8.65	8.78	8.98	9.25	8.53	8.51	8.58	8.71	8.90	9.18
203.000	8.54	8.52	8.60	8.72	8.90	9.16	8.44	8.42	8.49	8.61	8.79	9.05
222.000	8.11	8.09	8.16	8.27	8.44	8.68	8.01	7.99	8.06	8.17	8.34	8.57

Also, the creation of such a hydroelectric power plant is important in terms of environmental protection. Thus, by selling the energy obtained from here to another enterprise or company, the CO_2 emission factor thrown into the environment using fossil fuels of that area is prevented.

Abstract

Mudslides, as well as the manifestation of landslides, rockfalls, desertification of the territory, seasonal floods, hail, are one of the negative natural processes that manifest themselves in the mountainous regions of the republic, damaging communications. Villages are also formed in parts of areas that economically represent only areas of mountain grazing, are poorly populated or not populated at all, but nevertheless do not lose their relevance and, like other inhabited areas, require studying the manifestations of natural processes. The amount of precipitation and the level of moisture in the mountainous part of the republic are the highest, so the influence of moisture on the surface shapes is the most significant here. The territory of the Argun River basin is located in a zone of 5-7-point seismicity, which increases from north to south. The most populated Chechen inclined plain and the northern slopes of the Greater Caucasus are located in a zone of increased seismic activity. An assessment of the possible activation of mudflow processes as a result of climate change is given. The conducted qualitative analysis of changes in meteorological factors influencing the formation of mudflows (precipitation, temperature regime) in the region according to data from various weather stations. An increase in air temperature and an increase in the amount of precipitation — both average annual values and values for the warm and cold period - have been revealed; the tendency of glaciers to retreat is clearly observed. A study of climate change over a long period shows that mudflow activity in the Argun River basin has increased significantly.

Keywords: mudflow processes, climatic changes, precipitation, temperature regime.

I. Introduction

The borderline natural and geographical position of the republic at the junction of the large European plains and the powerful mountain system of the Greater Caucasus determines many of its features. All elements of the natural landscapes here are formed under the influence, on the one hand, of the barrier role of the mountain system from the south, as a result, subtropical warm air masses do not penetrate into the territory of the republic, moisture intake to the flat part from the air basins of the Black and Mediterranean Seas decreases. On the other hand, the complete openness from the north, north—west and east to the penetration of Arctic, Atlantic and continental Siberian, Central Asian air masses in different periods of the year determines the aridity of the northern and moisture-sufficiency of the foothill plains of the republic with a generally high level of solar insolation.

The combination of all these factors determines the vegetation cover and fauna and, with their participation, the formation of landscapes over the previous millennia, which we see in the republic from north to south today. The variety of natural landscapes and, accordingly, soil-climatic, orographic and other conditions in the republic, from the northern lowlands to the snow-covered highlands in the south, create favorable conditions for human activity. Within the republic, he can choose a place of residence in a wide variety of natural conditions, which in many places have unique properties that contribute to health, its restoration and longevity. Tectonically— it is a large monocline complicated by anticline folds, the largest of which are the Benoy in the east and the Dattykh between the Fortanga and Assa rivers in the west. Reaching a width of up to 30 km in the western part, the Black Mountains noticeably narrow to the east, where their width does not exceed 12-15 km. The system of low-mountain ranges of the Black Mountains is composed of Cretaceous and Paleogene limestones, marls and sandstones, which are easily exposed to surface (exogenous) destruction. As a result, the Black Mountains have soft, rounded outlines. The ridges are low, the prevailing heights are 1000-1100 meters, they represent a series of mountain folds gradually descending to the north. Transverse valleys formed by numerous rivers and longitudinal depressions divide the Black Mountains into a number of separate mountain ranges. River valleys often expand, and the mountains surrounding them seem to recede, forming vast basins in places. The largest of these basins in the Black Mountains is located at the confluence of the Chanta-Argun and Sharo-Argun rivers, near the village of Chishki. From the foot to the peaks, the Black Mountains are covered with forest, which gives them a dark color from afar. Hence their name. The Black Mountains represent a zone of foothills. The actual mountainous part of the republic is located on the northern slope of the Greater Caucasus.

In the sedimentary thickness of the Caucasian Ridge, strong and easily destructible rocks alternate, which led to their division into a number of longitudinal ridges. Ridges were formed where resistant rocks were exposed, and valleys separating them arose in places where less durable rocks spread. The pasture Ridge (next to the south of the Black Mountains) has a complex structure. In the western part, it forms two, and in some places three parallel ridges. Strata of Upper Cretaceous limestones, dolomites, marls are exposed to the south by a steep cliff, and in the north they fall gently at a slight angle (up to 140). Many peaks of the Pasture Range rise to a height above 2000 meters. The next one to the south is a Rocky ridge, which is especially distinguished by its asymmetry: the southern slopes are steep, almost vertical in many areas, and the northern ones are gentle. In the valleys of the rivers crossing the limestone ridges, narrow and extended sections alternate.

In places where the river cuts into the solid limestone rocks composing the ridges, its valley has the appearance of a deep narrow gorge with steep rocky slopes. Even on a hot, sunny day, twilight and coolness reign in the gloomy gorges of such a gorge. The river valleys in the gaps between the ridges are completely transformed. Here, the mountains form vast light basins, elongated, as a rule, along the course of the river. Mountain villages and villages are usually located in such places convenient for settlement. Along the southern border of the republic stretches a chain of silvery-white snow-capped peaks of the Lateral Ridge, which in this area is a thousand meters higher than the Main Caucasian Ridge.

Between the Lateral Ridge and the Rocky One (to the north) is the North Jurassic intermountain basin, which reaches its greatest width to the west, within the Central Caucasus (up to 35 km) and within the republic is manifested by a number of separate basins: Galanchozhskaya, Itum-Kalinskaya, Sharoyskaya, Makazhoyevskaya. The lateral and Watershed (Main) ridges are composed of lower — Middle Jurassic Mesozoic clay shales. In the Chechen Republic, the links of the Lateral Ridge are the Pirikitelsky ridge with the peaks of Tembolt-Lam (Tebulos-Mta), Kamito-Dattakh-Kort (4271m), Donos-Mta (4178m) and the Snow Ridge, the highest point of which is Mount Diklos—Mta (4274 meters). Eleven peaks in Chechnya have a height of more than 4,000 meters. Tembolt Lam peak (4494 m above sea level) is the highest not only in Chechnya, but also in the entire Eastern Caucasus. Exogenous (external) factors that form the morphological appearance of the relief include: water, climate, fauna and flora, human activity, and the nature of rocks on the surface. Their influence is complex, zonal or altitudinal. In the Chechen Republic, the relief of the highest mountains in the south is directly determined by eternal snow and ice. The formation of mudflows in the Chechen Republic is due to a combination of geological, climatic and geomorphological conditions: the presence of seleforming soils, sources of intensive watering of these soils, as well as geological forms contributing to the formation of sufficiently steep slopes and channels.

III. Results and discussion

The Argun River basin is characterized by the complexity of the surface structure, which is associated with the tectonic structure and geological history of development. This has a decisive effect on orohydrography, climatic conditions, in particular precipitation and temperature conditions, which naturally contributes to a high probability of mudflow processes. The abundance of precipitation contributes to an increase in the moisture content of rocks, significantly increasing their mass and increasing the effects of gravitational forces on soil masses, this leads to the rupture of strong structural bonds in rocks, changing the consistency of soils to plastic and even fluid. Reduction of structural bonds in rocks on slopes, forming dynamic changes in slope landscapes.

In various regions of the republic, with abundant precipitation, only a small part of the moisture is infiltrated, and most of it quickly flows down the slope. In the areas of permafrost, rapid and deep thawing of frozen rocks in spring and summer favours the development of mudflows: on the slopes of the northern exposure to solifluction phenomena, on the southern ones — outflows, which, with abundant precipitation, can turn into active mudflows. Argun Gorge is one of the most dangerous mudslides in the Chechen Republic. The zone of occurrence of mudflow processes here are both the channels of numerous tributaries of the Argun themselves, as well as the channels of temporary watercourses, which, with prolonged precipitation, often turn into violent water-mud flows (Figure 1).

The physical and mechanical properties of the constituent territories of the Argun Gorge determine the features of their destruction during the active regime of atmospheric precipitation, the nature of which undergoes significant changes under the influence of ongoing changes in the planet's climate. Geological and geomorphological processes of exogenous origin depend on the resistance of rocks with different strengths to external influences. Our research has shown that over the past decade, there has been a significant intensification of mudflow processes in the study area due to ongoing climate changes.

The study area is composed of loose rocks of Neogene age that are easily susceptible to destruction, therefore even slopes and hollows with a small slope are potential zones of mudflow generation. The Argun River basin belongs to the zone of significant waterlogging, where the annual amount of precipitation is 700-1100 mm or more. Mudflows arising in the upper reaches of the Argun River basin consist of a mixture of water, clay and pebbles.

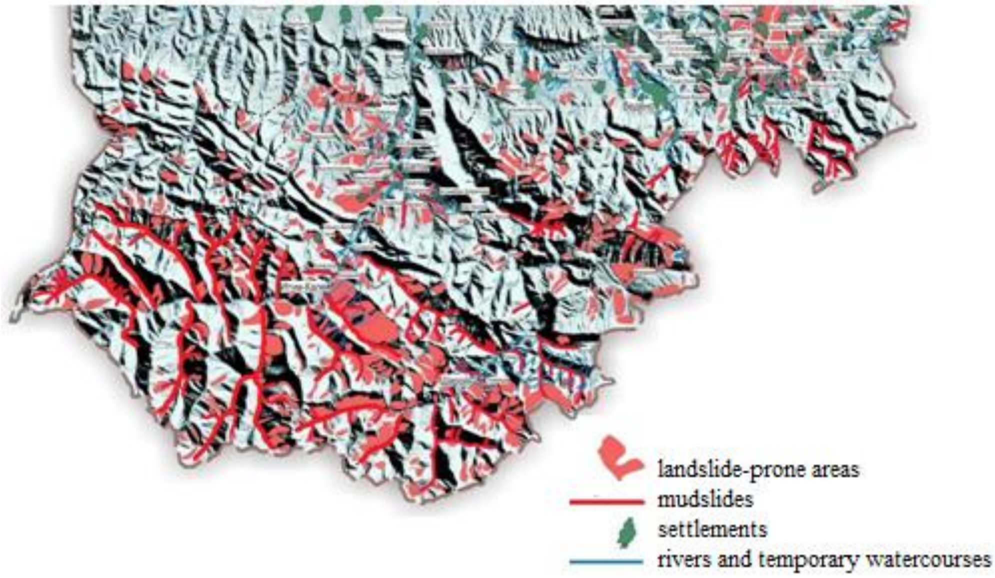

Figure 1: Map of catastrophic natural processes in the Chechen Republic

The ongoing mudflow processes in the Argun River basin belong to the rain by their genesis. The snow and glacial type of mudflow processes in the basin are manifested in the high-altitude part.

Sources of solid nutrition of mudflows can be: glacial moraines with or without loose filling; riverbed blockages and clutter formed by previous mudflows; woody and vegetative material. Sources of water supply for mudslides are: rains and downpours; glaciers and seasonal snow cover (during the melting period); waters of mountain lakes. Glacial mudflows are also characteristic of high-altitude basins with developed modern glaciers and glacial deposits, such as the upper part of the Sharo-Argun and Chanta-Argun rivers and their tributaries.

The main source of their solid nutrition are moraines, which are involved in the process of mudflow formation during the intensive melting of glaciers. The immediate causes of mudslides are also the intense melting of snow and ice, less often earthquakes. For the formation of mudflows, it is necessary to have: a sufficient number of products of rock destruction on the slopes of the basin; a sufficient volume of water to flush or demolish loose solid material from the slopes and its subsequent movement along the channels; a steep slope of the slopes and watercourse. The manifestation of mudflows forms the dynamics of the landscapes of the upper Chanta-Argun. The stability of subalpine and mountain-steppe landscapes is disrupted, the underlying rock is exposed, vegetation and a fertile layer flow down together with the mud mass, transferring subalpine and mountain-steppe landscapes into mudslides.

The prediction of glacial mudflow hazard is based on the identification of abnormal deviations in the characteristics of water and thermal regimes. For this purpose, information from hydrometeorological stations and posts located in this mountainous area is used. The forecast of glacial mudflow hazard consists in predicting in advance the possibility of a breakthrough of moraine and dammed lakes, as well as intraglacial reservoirs. According to the composition of the transferred solid material, mudflows are usually distinguished as follows: mudflows, which are a mixture of water and fine earth with a small concentration of stones (volume weight of the stream is 1.5–2.0 t/ m3); mudstone flows, which are a mixture of water, fine earth, pebbles, gravel, small stones; large stones are also found, but there are few of them, they sometimes fall out of the stream, then begin to move with it again (the volume weight of the stream is 2.1–2.5 t/m3); water-stone streams, which are a mixture of water with mostly large stones, including boulders and rock fragments.

The area of the upper reaches of the Sharo-Argun River basin is characterized by a fairly high mudflow activity. The area belongs to the waterlogging zones. Two factors affect the mode and amount of precipitation here: atmospheric circulation and the presence of high ridges of the Caucasus Mountains, which increase precipitation in its mountainous part.

Precipitation by season is characterized by great unevenness, due primarily to the intrusion of moist air masses into its limits, which are brought by the Atlantic cyclone. Since the influence of the Atlantic cyclone is manifested in the North Caucasus mainly in summer, the highest humidity and maximum precipitation are observed in May — July. At the same time, there is a sharp decrease in their annual number in the direction from south to north — from the mountains to the plains.

The amount of precipitation in the mudflow-prone zone of the Chechen Republic per year is 800-1000 mm or more. Mudflows arising in the upper reaches of the Sharo-Argun River basin consist of a mixture of water, clay and sand particles. The solution has the properties of a plastic substance. The stream seems to represent a single whole. Unlike a water stream, it does not follow the bends of the riverbed, but destroys and straightens them or passes over an obstacle. In places where there are significant riverbed slopes, the presence of loose material or clay, easily collapsing rocks, small sedimentary mudflows are formed caused by heavy rainfall of high intensity.

For the development of mudflow manifestations, in general, in the Argun River valley, hemorphological features contribute: a direct erosive-tectonic relief with a clear morphological reflection of the structural elements of the Montenegrin monocline, disturbed by the latest Neogene folding (anticline protrusions and flexures); the relief of the territory is relatively young, actively forming in the confrontation of intense modern uplifts and progressive erosion. increased precipitation from 800 to 1000 mm or more. per year. Moistening of rocks increases their mass and, accordingly, the effect of gravitational forces on them, which is accompanied by a weakening of the strength of structural bonds in them, a change in the consistency of soils to plastic and even fluid.

All this leads to a decrease in the strength (friction and adhesion) of rocks on the slope. With the stormy nature of precipitation, only a small part of the moisture is infiltrated, and most of it quickly flows down the slope. Also, the formation of mudflows is associated with anthropogenic activities in mountainous areas, construction and excessive grazing of livestock. According to the genesis, three main genetic types of mudflows are distinguished: rain, snow and glacial, which have a zonal distribution and significant differences in the mudflow regime.

The genetic type of mudflows characterizing the area means the dominance of this type of mudflows here and does not deny the presence of rare mudflows of a different genesis. In the mudflow basins of the Argun River, all three genetic types of mudflows are formed, but most of them belong to the rain type. Sedimentary mudflows are formed here with the transformation of mudstone flows as they move along the main channels. Spring activation of slope processes is possible during the cold autumn-winter season, when precipitation accumulates in the form of snow, initially falling on the unfrozen ground. In this case, during the spring snowmelt, almost all the meltwater will be filtered into the ground.

The precipitation of snow on the frozen ground will cause the predominance of surface runoff over infiltration during its spring melting. The nature of the influence of waterlogging is largely determined by the physical and mechanical properties of rocks, the peculiarities of their change when changing the regime of climatic indicators. Thus, under the same weather, the development of exogenous geological processes occurs differently in rocks of different genesis, with different strength properties, weathering rate, water resistance, etc.

IV. Conclusion

Mudflow processes are widely developed in the territory of the Argun River basin in the Chechen Republic in the medium- low-mountain and high-mountain terrain. With active climate change, it is possible to predict a high degree of mudflow activity in the high-mountain and medium-low-mountain parts of the Argun River basin.

The main factors of the predicted mudflow activity are climatic, to a lesser extent anthropogenic and technogenic. When abnormally heavy heavy rains fall, high activity of mudflow processes is possible in the middle-low mountains, in the middle and upper reaches of the Argun River and its tributaries. Mudflow activity is highly likely to occur in mudflow-prone areas in the middle and upper reaches of the rivers of the Argun River basin. Linear infrastructure objects (highways, communication lines, power lines, gas pipelines), parts of settlements fall into the impact zone of landslides. Climatic changes that have led to a change in meteorological indicators to an increase in atmospheric precipitation will lead to an increase in the number of mudflow processes in the Argun River basin.

Abstract

This article presents a systematic approach to the study of the relationship between natural disasters, ecosystems, pollution and sustainable development. The study is based on an analysis of the available data, as well as the latest scientific research in this area.

The main focus is on identifying the main causes of natural disasters and their impact on ecosystems, which, in turn, leads to environmental pollution and disruption of sustainable development. The authors of the study propose a number of recommendations and measures that can be used to make informed decisions and move towards sustainable development in a disaster risk environment.

In particular, the study focuses on the importance of taking environmental and social factors into account when developing disaster risk management strategies and ensuring sustainable development. This includes the development and implementation of effective measures to reduce the environmental impact on the environment, ensuring social justice and equality, as well as strengthening institutional mechanisms and structures for risk management.

In order to achieve sustainable development, it is necessary not only to eliminate the consequences of natural disasters, but also to prevent their occurrence in the future. This requires an integrated approach that will take into account the interrelationships between various factors such as climate change, environmental processes and socio-economic conditions.

Keywords: natural disasters, ecosystems, pollution, sustainable development

I. Introduction

The page of human history is filled with numerous natural disasters such as earthquakes, floods, hurricanes and fires. These natural disasters not only threaten people's lives, but also have a serious impact on the environment and ecosystems. In recent years, the frequency and intensity of natural disasters have increased significantly, which poses serious challenges to sustainable development.

One of the main problems associated with natural disasters is the destruction of ecosystems. As a result of strong earthquakes or floods, natural habitats of animals and plants can be completely destroyed. This leads to loss of biodiversity and imbalance in ecosystems. Many species of animals and plants that are important links in food chains and perform important functions in ecosystems may be completely extinct. This can have serious consequences for other species and for the ecosystem as a whole [1].

Another problem associated with natural disasters is environmental pollution. Chemical emissions such as oil spills or emissions of hazardous substances from factories can occur during natural disasters. This pollutes the soil and water, which can lead to poisoning of animals and plants. In addition, environmental pollution can cause long-term consequences, such as deterioration of soil and water quality, which leads to limited resources and complication of ecosystem restoration processes.

The impact of natural disasters on ecosystems can also lead to disruption of the cycles of nutrition and processing of organic matter. Natural processes, such as the decomposition of plant waste, contribute to the formation of nutrients for plants and further enrich the soil. However, as a result of natural disasters, these processes can be disrupted. For example, flooding can erode soil, carry away plant residues and deprive ecosystems of the necessary resources for restoration.

For sustainable development, it is necessary to develop strategies and take measures to adapt ecosystems to natural disasters. Important steps are the creation of nature reserves and nature reserves to preserve unique ecosystems in which species that require special attention for conservation can develop. It is also necessary to strengthen natural barriers, such as forest belts or reef systems, to mitigate the effects of floods and hurricanes.

However, it must be borne in mind that natural disasters cannot be completely prevented. Therefore, it is equally important to develop strategies for ecosystem restoration after natural disasters. Not only agriculture, but also forestry, fishing and other economic activities must take into account the long-term effects of natural disasters and their impact on ecosystems. [6,7].

Solving the problem of the impact of natural disasters on ecosystems requires an integrated approach and concerted efforts by States, international organizations and the public. It is necessary to conduct scientific research and develop new technologies to adapt ecosystems to changes caused by natural disasters [1]. In addition, the general public should be aware of the importance of ecosystem conservation and the need to take decisive steps for sustainable development. If we don't do this today, the consequences will be catastrophic for our planet and future generations.

II. Methods

One of the important methods that researchers can use is modeling. Using computer models, it is possible to study various scenarios of the impact of natural disasters on ecosystems, as well as to assess the effects of pollution on various components of the environment. Modeling makes it possible to predict the possible effects of climate change carry out risk calculations and develop appropriate strategies.

When studying this issue, a key aspect is the analysis of the impact of natural disasters and pollution on ecosystems. Various types of ecosystems are used for research - polar and temperate, oceans, forests, water resources and other elements of the natural environment. The assessment of the devastating impact of natural disasters makes it possible to determine the vulnerability of various ecosystems and develop effective measures for their conservation and restoration. An important aspect of the article is also the analysis of environmental pollution and its impact on ecosystems.

The study of various sources of pollution, including industrial emissions, vehicle emissions, as well as agriculture, allows us to identify priority areas in the fight against this problem. The main goal is to develop innovative and environmentally friendly technologies, as well as to take measures to reduce emissions and improve energy efficiency.

III. Results

Natural disasters such as hurricanes and floods are one of the main threats to ecosystems and sustainable development. In recent years, the number of such disasters has increased, which has led to serious environmental pollution and destruction of ecosystems. Pollution is also a serious problem, as it is caused by various sources such as industrial enterprises and transport. For many centuries, people have had the most negative impact on the state of the environment around us.

To date, the ecological state of the planet has forced humanity to begin taking active actions to maintain the current state and gradual recovery.

Table 1 shows us the dynamics of greenhouse gas emissions by sector from 2005 to 2021.

Table 1: *Greenhouse gas emissions by sector (million tons of CO2 equivalent per year).*

Greenhouse gas emissions are one of the main factors affecting climate change and ecosystem disruption. They lead to global warming, which, in turn, causes many negative consequences for the environment and sustainable development of countries.

Sectoral analysis of greenhouse gas emissions shows that the most significant sources are energy, industry and transport. Each of these sectors contributes to the disruption of the ecosystem and ultimately affects the sustainable development of the country.

Energy - Greenhouse gas emissions from energy account for approximately 73-77% of total emissions. This is mainly caused by the use of fossil fuels - coal, oil and natural gas. This leads to atmospheric pollution and disruption of climatic conditions.

Industry - Emissions from industry account for about 12-16% of total emissions. Atmospheric pollution occurs due to the use of fuel in the production process, as well as due to emissions from industrial enterprises.

Transport - The transport sector is the third largest source of greenhouse gas emissions. This is due to the use of cars, airplanes and other modes of transport that emit carbon dioxide and other harmful substances into the atmosphere.

The impact of greenhouse gas emissions on the sustainable development of countries is manifested in the following aspects:

Climate change - greenhouse gas emissions cause global warming, which, in turn, leads to negative consequences such as sea level rise, droughts, floods, hurricanes, etc. These climate changes disrupt the ecosystem and make it less habitable.

Economic losses - greenhouse gas emissions also have a negative impact on the economy. For example, they can lead to lower crop yields, which in turn can cause food shortages and economic problems. In addition, climate change can lead to damage to infrastructure such as roads and bridges, which can also affect the country's economy.

In order to minimize the impact of greenhouse gas emissions and ensure the sustainable development of countries, it is necessary to take measures to reduce emissions and adapt to climate change. This may include switching to cleaner energy sources, improving energy efficiency, developing public transport, etc.

A source: https://rosstat.gov.ru [5]

Table 2 shows us the dynamics of the number of natural disasters that occurred on the territory of the Russian Federation in 2010-2021.

In 2023, the number of dangerous weather events in Russia increased by 22%. Experts define such phenomena as a threat to human health or significant economic damage. Among them are abnormally high or low temperatures, heavy rains, hurricanes, floods, droughts and forest fires. Last year, 1,191 natural disasters were recorded, compared with 976 in the previous year. The year 2023 took the second place in this indicator in the history of observations of the Hydrometeorological Center, second only to 2021, when 1,205 dangerous phenomena were registered. During this period, only the number of days with abnormal heat decreased by 48% [5].

Any natural disaster brings with it significant losses both in material and human terms.

Let's discuss the Kashmir earthquake that occurred on October 8, 2005 at about 8:50 a.m. local time. This earthquake was rated at 7.6 on the Richter scale and led to the destruction of many buildings. The capital of Kashmir was severely damaged, killing more than 10,000 residents of the city. As a result of the disaster, the main minaret of the mosque was also destroyed.

This earthquake is considered one of the most severe in South Asia. About 4 million people were left homeless, and more than 30,000 buildings were destroyed. Pakistan has suffered huge financial losses estimated at 12 billion US dollars [3].

Let's also consider the flood that occurred in the Irkutsk region in 2019. The Oka River in the city of Tulun has reached its maximum level of 14 meters (with an acceptable value of 700 cm). Scientists called the cause of the flood the heavy rains that have recently fallen in the region. The only highway connecting Moscow with Siberia and the Far East was damaged, and more than

6,000 houses were flooded. The financial damage to the region was estimated at more than 27 billion rubles. The authorities of the Irkutsk region announced the day of remembrance of the victims of the flood on July 12, 2019.

Terrible floods have occurred in the Sochi region and some areas of the Krasnodar Territory. Due to the prolonged rains, as much precipitation fell in a day as usually falls in a whole month. Rivers overflowed their banks, flooding residential buildings and boarding houses, roads and highways in villages were seriously damaged. Three weeks later, the scenario was repeated: another month's rainfall, new floods and people died.

In regions with extremely high levels of environmental stress, a significant part of the territories already exceed the permissible limits of the economic capacity of ecosystems. In areas with a high level of environmental stress, these limits have not yet been reached, but they are approaching. Continuing to increase production in these conditions at current levels of technology and economic structure will lead to complete degradation of natural systems, complete exhaustion of resource opportunities, and the formation of sustainable sources of diseases among the population.

In areas with a relatively high level of environmental stress, the economic capacity of ecosystems is mostly exhausted. Changes in the economic structure are needed, taking into account the use of new technologies, the construction of wastewater treatment plants and the restoration and reclamation of landscapes.

Areas with an average level of environmental stress retain the economic capacity of ecosystems. It is possible to maintain the current economic structure, provided that new technologies are introduced and treatment facilities are created.

Regions with a relatively low level of environmental stress make it possible to continue increasing production and partially develop new territories that are not included in the system of specially protected natural zones.

In regions with low or very low levels of environmental stress, the full economic capacity of ecosystems is maintained according to the Concept of Sustainable Development of the Russian Federation.

The National Security Strategy of Russia until 2020 (Strategy 2020) was approved by Decree of the President of the Russian Federation dated 05/12/2009 No. 537 and includes section IV "Ensuring national security", where there is a special subsection 8 "Ecology of living systems and effective use of natural resources".

The 2020 Strategy focuses on the fact that national security in the environmental sphere is influenced by such negative factors as the depletion of world reserves of mineral, aquatic and biological resources and the presence of ecologically unfavorable regions in Russia. In addition, national security in this area is complicated by the presence of a large number of hazardous industries that violate the ecological balance, including non-compliance with sanitary, epidemiological and sanitary standards for drinking water. Radioactive waste from the non-nuclear fuel cycle remains outside regulatory regulation and control. All this leads to an increase in the strategic risk of depletion of the country's most important mineral reserves and a decrease in the production of many key minerals.

IV. Discussion

The Russian Federation is actively working to reduce the negative impact of natural disasters and pollution on the sustainable development of the country. The measures taken to do this include:

• Creation and implementation of programs to prevent and minimize the consequences of natural disasters, as well as to restore territories after them. Within the framework of these programs, measures are being taken to strengthen infrastructure, prepare the population for action in extreme situations, organize timely notification and evacuation.

• Improvement of the system of monitoring and forecasting of natural disasters. Modern technologies and tools are used to track natural disasters and provide early warning about them. This makes it possible to take measures to protect the population and reduce possible losses [3].

• Implementation of environmentally friendly and energy efficient technologies. This includes the development and use of renewable energy sources, reducing emissions of pollutants into the atmosphere and water bodies, as well as waste disposal.

• Development of the system of environmental protection and control over compliance with environmental legislation. This includes conducting regular inspections at enterprises and organizations, as well as imposing fines and other sanctions for violations of environmental norms and rules. Conducting educational and awareness-raising programs aimed at improving the ecological culture of the population. This includes environmental lessons in schools and universities, thematic events and actions, as well as information through the media.

• Cooperation with international organizations and countries to share experience and knowledge in the field of prevention and elimination of consequences of natural disasters and environmental pollution. All these measures are aimed at ensuring the sustainable development of the country, preventing the negative consequences of natural disasters and protecting the environment from pollution.

In addition, other actions are being taken:

Firstly, programs are being developed and implemented to prevent and minimize the consequences of natural disasters, as well as to restore territories after their impact. Measures are being taken to strengthen infrastructure and prepare the population for action in extreme conditions.

Secondly, the system of monitoring and forecasting of natural disasters is being improved using modern technologies and tools. This allows you to warn in advance about possible natural disasters and take measures to protect the population.

Thirdly, environmentally friendly and energy-efficient technologies are being introduced, including the development and use of renewable energy sources, and the reduction of pollutant emissions.

The system of environmental protection, monitoring compliance with environmental legislation and conducting educational programs to improve the ecological culture of the population is also being developed.

Finally, cooperation is being carried out with international organizations to share experience in the field of prevention and elimination of consequences of natural disasters and protection of the environment from pollution.

RISK MANAGEMENT USING ARTIFICIAL INTELLIGENCE IN THE ORGANIZATION OF CONSTRUCTION AND ERECTION OF MONOLITHIC REINFORCED CONCRETE STRUCTURES IN THE FAR NORTH AND ARCTIC ZONE CONDITIONS

Azariy Lapidus, Tembot Bidov, Alan Khubaev, Roman Samsonov

•

National Research Moscow State Construction University, RUSSIA
KhubaevAO@mgsu.ru

Abstract

The study is focused on the application of artificial intelligence (AI) in the construction and erection of monolithic reinforced concrete structures in the Far North and Arctic zone, with the aim of managing potential risks. The topic deals with various ways required to mitigate risks associated with the unique climatic and weather conditions of these regions. The objective of this study is to develop a methodology for forecasting and risk management using AI.
In this study, data on construction processes and potential risks in Far North and Arctic zone conditions was utilised. The methodology is based on the application of artificial intelligence algorithms for data processing and analysis.
The study resulted in the proposal of an AI-based risk management methodology. This methodology enables the prediction of potential issues and comprehensive risk management at all stages of construction and erection of monolithic reinforced concrete structures.
The application of AI in construction risk management in the Far North and Arctic zone increases the efficiency and safety of construction processes. The use of the developed model is recommended for risk minimization and optimization of construction in complex climatic conditions.

Keywords: Risk management, artificial intelligence, monolithic reinforced concrete structures, Far North, Arctic zone, risk forecasting

I. Introduction

The construction and erection of monolithic reinforced concrete structures in the Far North and Arctic zone presents a number of significant risks, including those associated with harsh climatic conditions, limited availability of resources, and complex logistics [1-6]. It is of the utmost importance to manage these risks in order to guarantee the safety, quality, and efficiency of construction projects in these regions.

The organization of construction and erection of monolithic reinforced concrete structures in the Far North and Arctic zone presents a unique set of risks, largely due to the harsh climate, limited access to resources, and specific reliability and durability requirements. [7,8] Further discussions will be undertaken to evaluate all types of risk.

1. Climate risks:

- Low temperatures: Paving concrete at sub-zero temperatures requires specific steps such as heating the concrete mix placed in the formwork, using anti-freeze additives, and insulating the formwork. Failure to comply with these technical requirements may result in failure to achieve the design strength of the concrete, cracking and other defects.

- Strong winds: Strong winds can impede the operation of construction equipment, prevent concrete from gaining strength, damage building structures, and increase the risk of accidents.

- Snow drifts: Snow drifts can impede access to the construction site and delay delivery of materials and equipment.

- Polar Night: Limited visibility during polar night can impede work and increase the risk of accidents.

2. Logistical Risks:

- Remoteness from suppliers: Delivery of materials and equipment can be difficult and expensive in remote areas of the Arctic. [9,10]

- Limited access to transportation infrastructure: Lack of roads, ports and airfields can make it difficult to deliver supplies and move personnel. [11,12]

- Dependence on weather conditions: Transportation of cargo on snow-covered roads may be difficult during winter.

3. Technical Risks:

- Permafrost: Construction requires the use of special foundation solutions to prevent subsidence and deformation of structures. This issue requires particular attention in light of the current global warming trend.

- Seismic activity: Some areas of the Arctic are subject to seismic activity, therefore seismic loads in the design of structures shall be taken into consideration [13-15].

- Corrosion: The presence of salty seawater and corrosive atmospheres can accelerate the corrosion of metal structures.

4. Personnel-related risks:

- Extreme conditions: Working in the Far North and Arctic zone can be physically and psychologically challenging, as such can lead to decreased productivity and increased risk of accidents.

- Lack of qualified specialists: It can be challenging to identify, recruit and retain qualified professionals willing to work in extreme conditions.

5. Economic Risks:

- Significant construction costs: Projects pertaining to the construction of facilities in the Arctic is associated with significant coast implications related to logistics, materials, equipment, and labor.

- Price instability: It is possible that prices for construction materials and other related services fluctuate, which could result in budget overruns.

- Potential for delays: Delays in deliveries, weather and other factors can result in construction delays, which in turn can increase costs.

It is of ~~the~~ utmost importance to manage these risks effectively in order to ensure successful construction in the Far North and Arctic zone. The use of AI can help identify, analyze, and manage risks, thereby improving construction efficiency and safety.

Traditional risk management methods are not always effective in addressing the increasing complexity and uncertainty of factors in extreme conditions in the North. The application of advanced technologies, such as artificial intelligence (AI), can be regarded as an invaluable opportunity to enhance the effectiveness of risk management in construction projects. [16-20]

While there is growing interest in the use of AI in construction, there is still a lack of research on its application in extreme conditions, such as those found in the Far North and the Arctic. Implementation of AI in construction can resolve problems in the following key areas:

- **Improving construction efficiency:** Artificial intelligence (AI) can optimize planning, logistics, resource management, and quality control, thereby reducing construction time and costs.

- **Improving structural quality:** AI systems can analyze data on weather conditions, material properties, and manufacturing processes to assist in decision-making, thereby improving the reliability and durability of structures.

- **Workplace safety:** AI can be utilized to monitor the condition of construction projects, predict potential risks, and automate hazardous operations, thereby enhancing worker safety.

The objective of this article is twofold: firstly, to assess the potential of AI in the organisation of construction and erection of monolithic reinforced concrete structures in the Far North and Arctic zone; secondly, to identify key problems and areas for further research. The research will propose a risk management methodology and methods for implementing it in the process of erecting monolithic reinforced concrete structures in the Far North and Arctic zone. [21-24]

II. Materials and methods

The scientific literature was analyzed as part of a study on the application of AI in construction. Additionally, case studies were conducted on the use of AI in other industries operating in extreme environments.

The following aspects were considered in order to evaluate the potential of AI in construction in the Arctic:

- **Planning and design:** The use of AI to optimize construction site selection, site-specific structural design, and cost forecasting.
- **Logistics and resource management:** The use of AI to optimize material delivery routes, manage inventory, and forecast demand.
- **Quality Control:** The application of AI to the analysis of data from sensors on construction projects enables the monitoring of structural health and the determination, identification and troubleshooting of defects.
- **Workplace safety:** By leveraging AI, we can predict potential risks, automate hazardous operations, and monitor the condition of personnel.

It is essential that risk management methodology be comprehensive and take into account both traditional approaches and the specific features of AI use in the context of AI application in the organization of construction and erection of monolithic reinforced concrete structures in the Far North and Arctic zone [24-28].

III. Results

The result of the research is the methodology of risk management when using AI in the construction of monolithic reinforced concrete structures in the Far North and Arctic zone, as presented below. This is an algorithm of step-by-step actions. Please refer to Table 1 for details.

Table 1: *Methodology of risk management when using AI*

№	Stage	Actions
1	Project Initialization	• Define project objectives and requirements. • Form a project team, including AI and construction specialists.
2	Data Collection	• Obtain data from completed projects in similar environments. • Analyze the available information on climatic conditions, logistics, material supply, and technical aspects.
3	Risk Identification	• Conduct brainstorming sessions with all stakeholders. • Utilize AI to analyze the collected data and identify potential risks.
4	Risk Assessment:	• Evaluate the likelihood and impact of each identified risk. • Apply an AI model to predict potential scenarios and their consequences.
5	Risk Mitigation Planning	• Develop a risk management strategy (avoidance, mitigation, transfer, acceptability). • Identify specific actions for each risk, including the reservation of necessary resources.
6	Implement the risk management	• Implement the risk management plan. • Assigning responsibility for monitoring and controlling risks.

	plan.	
7	Monitoring and Control:	• It is essential to regularly track the status of the project and any associated risks. • Use AI for continuous monitoring and early warning of problems.
8	Risk Response	• In the event of a risk, the implementation of response plans is to be initiated without delay. • Adjusting actions according to the current situation.
9	Analyze and adapt	• Analyze the effectiveness of risk management measures. • Modify risk management plans as needed.
10	Reporting and Communication	• Regular reporting of risk status and management actions. • Maintaining open communication about risks and risk management actions.
11	Project Completion and Learning	• After project completion, analyze the project with a focus on risk management. • Leveraging the insights gained to enhance the training of staff and optimize risk management processes in future projects.
12	Repeat the cycle.	• Apply the updated risk management methodology to future projects, taking into account lessons learned and new AI capabilities.

The process of collecting data on implemented projects begins with the identification of key indicators and risks that warrant analysis. Subsequently, questionnaires, interviews, and document analysis can be employed to procure data on previous projects. It is crucial to ensure anonymity of responses and to analyze the collected data in order to reveal trends and findings that will help in planning future projects.

Table 2: *Risk matrix*

№	Risk Description	Probability (P)	Impact (I)	Risk Class	Risk Indicator (R)	Management Measures
1	Delay in delivery of materials	High (0.8)	Medium (50,000 rubles)	High	40,000	•Close standby contracts •Create a stock of materials
2	Inconsistency in material quality	Medium (0.5)	High (100 000 rubles)	High	50 000	•Careful quality control at acceptance
3	Shortage of qualified personnel	Low (0.2)	Medium (20 000 rubles.)	Средний	4 000	•Contracting back-up contracts
4	Changes in legislation	Low (0.1)	High (200 000 rubles)	Medium	20 000	•Monitoring changes in legislation •Consultation with lawyers
5	Unexpected force majeure	Low (0.1)	Very high (500 000 rubles.)	very high	50 000	•Development of a plan of action in case of force majeure •Insurance against force majeure risks

The risk identification phase commences with the definition of project goals and objectives, followed by brainstorming sessions with the project team and stakeholders. It is also important to analyze past projects in order to identify potential problems and consider external factors that may affect the project. The next step is to generate a comprehensive list of all potential risks. This list will then be analyzed and classified according to the level of threat posed.

The risk assessment phase commences with the categorization of identified risks according to their level of likelihood and potential impact. A risk matrix can be utilized for this purpose, with each risk rated on a scale from low to high. For each risk, specific impact indicators are identified, such as financial loss, project delivery time, or reputational risks. A risk score is calculated for each element based on these scores, which allows the risks to be ranked in order of hazard.

The probability (P) is calculated using historical data, expert opinion, and an analysis of the current situation as presented in the table. Impact is estimated in monetary terms, in days of delay, or as a percentage of the planned outcome. The risk class is determined by combining probability and impact. The risk score (R) is calculated by multiplying the probability and impact factors together (P * I). Management measures have been defined for each risk, with the objective of minimizing or preventing it.

In the Monitoring and Control phase, AI is leveraged to facilitate continuous tracking and risk management. This encompasses a range of activities, including continuous data analysis, prediction and warning, decision optimization, automation, and data visualization.

In the seventh and eighth phases, the methodologies are employed to actively manage risks throughout the project lifecycle. The project team employs AI systems to monitor the situation continuously, analyzing large volumes of data in real time during the monitoring and control phase.

This allows for the timely identification of any deviations from the plan and potential threats. The risk response stage requires the ability to make quick and flexible decisions. In the event of an issue, the team promptly assesses the situation, activates pre-prepared response plans, and, if necessary, adapts them to the current circumstances. The AI's ability to rapidly simulate a range of potential scenarios is a crucial factor in enabling optimal decision-making in the challenging conditions of the Far North.

IV. Conclusions

The use of artificial intelligence in risk management may prove to be effective tool for managing risks in the construction of monolithic reinforced concrete structures in the Far North and Arctic zone. The use of AI enhances the precision of risk identification and assessment, optimizes decision-making, and facilitates real-time risk monitoring.

Further research could focus on improving data processing and analysis methods, developing AI models, and exploring specific aspects of risk management in different types of Arctic projects. The successful implementation of AI in construction in the Arctic requires:

- Create databases of construction in these environments that can be used to train AI models.
- Develop AI systems that are tailored to the specific operational conditions in the Arctic.
- It is essential to provide adequate training to qualified professionals who are capable of developing, implementing, and maintaining AI systems.

The set up of AI in construction in the Arctic is a complex system, but nevertheless a positive undertaking given the fact that it has the potential to drive significant progress in this field. We anticipate active development of AI in construction over the coming years. It is anticipated that AI development will include the Arctic. The advent of new AI technologies and tools, coupled with the growing accessibility of construction data in challenging environments, will drive the broader adoption of AI in this sector.

Abstract

The risk of depletion of oil and gas resources, which the countries of the world have been using for many years, is increasing over time. Also, considering that the oil and gas sector is one of the main causes of climate change, it is necessary to move away from this type of fuel. In this case, there is a need to use alternative and renewable energy sources in the world. The research area is located in the southeastern part of Azerbaijan, where mineral-thermal water deposits have formed. Mineral-thermal water deposits of the region are divided into 3 groups (Masalli, Lankaran and Astara). The northern zone (Masalli group mineral waters) was mainly formed in the section consisting of the alternation of Paleogene cracked sandstones - siltstone and argillite. These waters belong to the chlorinated-sodium-calcium chemical composition and the degree of mineralization in the amount of 17 g/l. The water temperature reaches 64-66 ^{0}C. The central zone (Lankaran zone) is mainly formed in the intersection of Eocene cracked tuff-sandstones, argillite and siltstones, it has a chlorine-sodium-calcium chemical composition, the degree of mineralization is 5-6 g/l, the temperature is within the limits of 50 ^{0}C, it is completely nitrogenous, hydrogen-sulphide. has a gas content. The southern zone (Astara zone) has high mineralization (20 g/l), chlorine-sodium-calcium chemical composition, nitrogen, methane and hydrogen-sulfide gas content, water temperature is within 50 ^{0}C. The mineral waters discovered in the research area can be used for therapeutic purposes. The thermal waters formed in the research area can be used as a source of renewable energy.

Keywords: geothermal, natural hazards, climate change, renewable energy, consumption

I. İntroduction

The Talish area of Azerbaijan is characterized by a mountainous terrain that descends sharply towards the Caspian Sea in the north-eastern direction. Astara passes through the southern part of the territory, and Alashar-Burovar anticlinorium passes through the northern part, and they are separated from each other by the North-West oriented synclinorium. These tectonic elements are overthrusts, faults, etc. as a result, it has become more complicated [1].

There are more than 50 mountain rivers in the study area, relatively large rivers are Vilashchay, Lankaranchay, Tangeruchay, Boladichay, Astarachay and others. In the summer months, the waters of the rivers are completely used for irrigation, only Vilashchay, Lankaranchay and Astarachay go back to the Caspian Sea.

In 1964-1970, geological exploration works were carried out to study thermal waters in Talish zone (Astara, Lankaran and Masalli), for this purpose, 17 exploratory wells were dug and thermal waters with a temperature of 38-64 ^{0}C were discovered in all of these wells.

In the eastern part of the territory, mineral waters belong to the chlorinated type, in the northern part they are accompanied by hydrogen-sulfide and methane, and in the southern part they are accompanied by nitrogen gases [2].

The Talish wrinkle system consists of 3 zones stretching from the north-west to the south-east at a distance of 100 km in the general direction of the Caucasus and is located on the border with the Islamic Republic of Iran. The peaks of Giz Yurdu (2438 m), Kamyurkey (2477 m) are located here. Parallel to this zone and older than them, the 2nd zone passes the Peshtasar mountain system. The 3rd Alasha-Burovar range runs parallel to the 2 zones mentioned above.

River valleys and terraces with a complex structure, various formation features and an ancient history of development have further complicated the relief of the Talish horst-anticlinal uplift and caused their sharp division. Tectonic fractures and faults are formed along the river valleys and play a leading role in the natural outflow of mineral waters.

The Talish zone is separated from the Little Caucasus by the Araz depression. From the tectonic point of view, Talish zone consists of Astara, Burovar anticlinories, Lerik, Yardimli, Jalilabad synclinors. These tectonic elements are further complicated by uplifts and faults. They are composed of Paleogene and Neogene sediments.

Volcanic eruptions occurred in Talish in the early Eocene, and pyroclastic materials were brought here in the Oligocene and early Miocene.

The Talish fold area is the immediate eastern continuation of the central part of the Lesser Caucasus. It is composed of thin carbonate of the Upper Cretaceous and flysch sediments of the Paleogene - Lower Eocene. The small intrusive masses of the area are located in the Paleogene and belong to the alkaline basalt, diabase-diorite and gabbro-monsonite-syenite formations and form a single magmatic complex together with the underlying volcanic rocks.

Tectonically, the Talish mountain system is included in the northern wing of the Elburus megaanticlinorium as a first-order anticlinorium. The Talish mountain system is bordered by the Kura depression in the north, and extends towards the Caspian Sea in the east [3].

Based on the analysis of electro and seismological geophysical materials, it was determined that the thickness of the Quaternary sediments is related to the deep tectonics of the area, the thickness of the structures increases in the synclines and decreases in the anticlinal parts.

The main structures of the area are in the Transcaucasian direction, it is bordered by the Kura megasyncline in the north, and the Lankaran plain in the east.

In general, the structures formed in the area differ from each other according to their metallogenicity, geotectonic development, and seismicity. Between the settlements of Goytepe and Masalli, there are two Goytepe-Masalli anticlines, stretched in the direction of latitude, at a depth of 2000-2700 m, and they alternate with the Gizilagac anticline. Lankaran anticline, which is 28 km long and 500 m deep, is located in the anticline zone indicated above from the southwest side.

II. Methods

According to the research carried out in the research area, two groups of mineral water are distinguished here:

1. Masalli-Lenkoran-Astara mineral water group;
2. Assisted mineral water group

Masalli-Lenkoran-Astara mineral water group is spread in the confluence zone of mountainous and plain areas. Here, mineral water sources are hot, and highly profitable [4,5].

To the north, highly mineralized (17 g/l) hypothermal (64 ^{0}C) waters were found in Masalli (Arkivan) mineral water sources. These waters are carbonated and hydrogen sulphide. This indicates that they are likely to be in contact with oil-bearing rocks. Masalli-Lankaran-Astara mineral-thermal water deposits are spread at the junction of mountainous area and plain areas. Here, in particular, thermal water deposits are located (Fig. 1) [6,7,8].

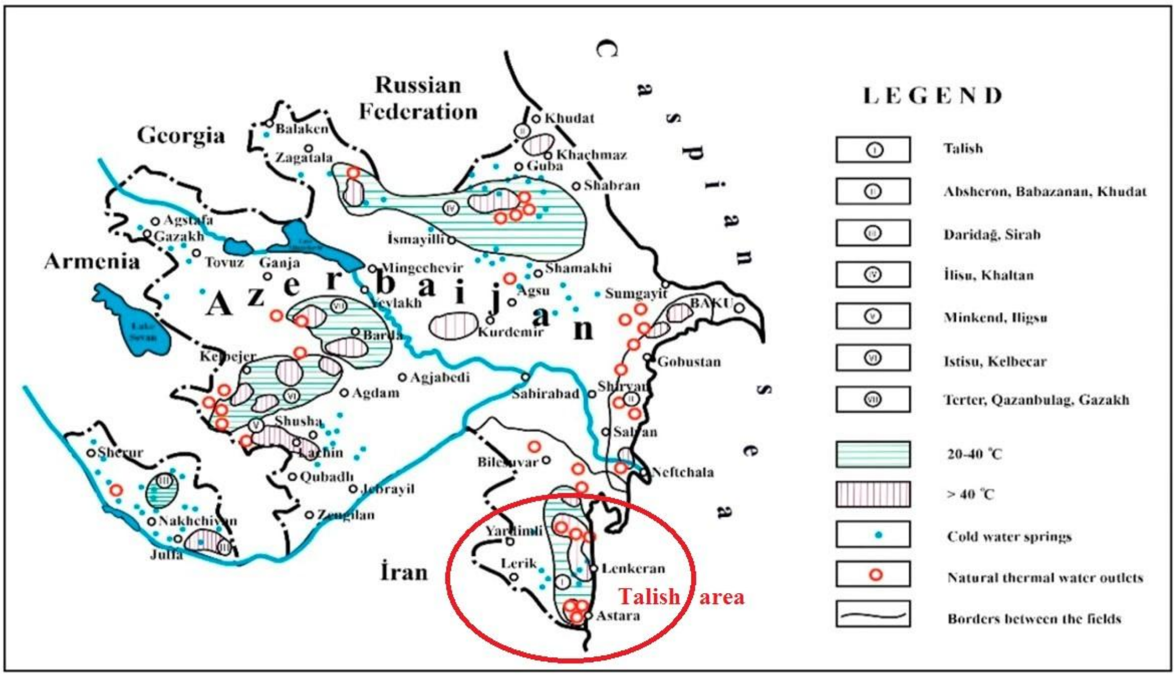

Figure 1: *Mineral-thermal waters map of Azerbaijan*

I. Masalli, (Arkivan) mineral water deposits are spread in the northern part of the territory. The degree of mineralization is 17 g/l, T-64 ^{0}C, carbon dioxide and hydrogen sulfide. This indicates that they are in contact with oil rocks [9,10].

II. There are Lankaran mineral-thermal water deposits in the central part of the area. The water temperature is 42-43 ^{0}C. The degree of mineralization is within 3 g/l. Waters contain nitrogen, sometimes accompanied by CO_2.

III. The temperature of thermal water deposits in the south of the area is 38-50 ^{0}C, the degree of mineralization is within 20 g/l. It is mainly accompanied by nitrogen gas.

Below is information about natural outlets and exploratory wells drilled in these areas:

1. Alasha area (Astara region), nitrogenous, mineralization rate 22 g/l, chemical composition Cl-HCO_3-Na-Ca. Among the specific components, H_2S, J elements can be mentioned. Its temperature is 46.2 ^{0}C, consumption is 1 million l/day. Of course, there are 3 exits. Wells with a depth of 500 m have been dug here. Total consumption is estimated at 2500 thousand l/day. In addition to the Alasha area, there are 6 natural water outlets in the Astara region. The chemical composition is mainly HCO_3-Cl-Na type. Total consumption is 2000 thousand l/day.

2. There are dozens of natural water outlets in Lankaran region. These are the following:

Meshesu thermal water field is nitrogen gas, the degree of mineralization is 3.9-5.9 g/l, and the temperature is 15.5-42.8 ^{0}C. The chemical composition is Cl-Na-Ca type. Among the specific components, H_2S is found in the trace of those waters. The total consumption is 1300 thousand l/day.

Ibadsu deposit - chemical composition is Cl-Na, mineralization rate is 3.6 g/l, temperature is 43-47 ^{0}C, consumption is 1 million l/day.

Gavzavua field - the degree of mineralization is 3.9-6.0 g/l, the chemical composition is Cl-Na type. Its temperature is 28 ^{0}C, consumption is 120 thousand l/day.

Khovt-Khaki deposit is an alternation of middle Oligocene siltstones and sandstones, chemical composition is Cl-Na type, methane (CH_4) gas. An exploration well with a depth of 1013 m was dug in this field. Temperature 22.5-37.4 ^{0}C, consumption 700 thousand l/day.

Sapnakaran area - for the first time, the location of the exploration well was chosen as a result of geophysical research, 10-15 m away from the natural outlets of mineral-thermal waters.

At a depth of 882 m, from the tuff sandstones of the Arkivan formation, the well produced a fountain (40 l/s), the temperature was 39 ^{0}C (the well was drilled with water, clay solution was used). Apart from those mentioned above, there are up to 20 natural outlets of mineral waters in Lankaran region; their temperature is 14-15 ^{0}C; the degree of mineralization was in the range of 0.6-8.8 g/l; chemical compositions are HCO_3-Cl-Na, Cl-HCO_3-Na-Ca.

Masalli district. Arkivan natural water outlet is characterized by alternation of upper Eocene siltstone, tuff sandstones and argillites.

H_2S from specific components; methane gas (CH_4); chemical composition – Cl-HCO_3-Na-Ca; mineralization rate 16.7 g/l; temperature - 41-50 ^{0}C; consumption is 1 million l/day.

Douzutan - natural water outlet - alternation of argillite, tuff sandstones and siltstones of the Upper Eocene; methane gas (CH_4); chemical composition is Cl-Na-Ca type; mineralization rate 17 g/l, temperature 63-64 ^{0}C, consumption 1.5 million l/day.

Itchy natural water outlet - alternation of Upper Eocene argillite, tuff sandstones and siltstones; chemical composition is Cl-Na-Ca type; spending 4 million l/day, its temperature is 66.1 ^{0}C (Table 1).

In addition, there are 7 natural water outlets in Masalli region. Their temperature is 15-52 ^{0}C. Mineralization rates are 0.9-17 g/l. Total consumption 1700 thousand l/day.

Table 1: *Physico-chemical and gas composition of mineral and thermal waters opened by search and exploration wells in Talish area*

Spring, wells	Depth, m	T, °C	pH	Degree of mineralization, g/l	Microelements	Gas composition

Gotursu	spring	64	7,8	14,16	Mn, Mg, Si, Al, Ti, Cu, Sr, Be	CH_4, N_2, He, Ar, O_2,CO_2, H_2, C_2H_6
Misharsu	spring	43	7,2	1240	-	CH_4, N_2, He, Ar, O_2,CO_2, H_2, C_2H_6

In the central part of the territory, the Lankaran group of mineral waters are found, which have a slightly lower temperature (42-43 ^{0}C) at the water outlets and a low degree of mineralization (3 g/l). These waters are mainly accompanied by nitrogen and sometimes carbon dioxide.

The South Astara mineral water group is hot (38-50 ^{0}C) and highly mineralized (20 g/l) and is mainly accompanied by atmospheric nitrogen (Table 2).

The eastern thermal-mineral waters of the area are chlorine-sodium-calcium, typical for oil regions. Here, the excess water in the north-west direction is cold, hydrocarbonate-calcium-magnesium-sodium type (Ag Korpu) and is accompanied by nitrogen gas.

Table 2: *Temperature parameters of the main natural thermal water springs of Talish area*

Springs	Consumption, m^3/day	Water temperature, ^0C	The amount of heat in the water coming to the surface of the earth	
			kkal.	mVt
Gotursu	3974	64	$1{,}53x10^{12}$	$6{,}4x10^{10}$
Donuzuten	1555	64	$5{,}98x10^{11}$	$2{,}5x10^{10}$
Misharchay	121	43	$2{,}44x10^{10}$	$10{,}2x10^{8}$
Bash Arkivan	302	50	$7{,}92x10^{10}$	$3{,}3x10^{9}$
Meshesu	112	38	$1{,}75x10^{10}$	$7{,}3x10^{8}$
Ibadsu	1123	42	$2{,}05x10^{11}$	$8{,}5x10^{9}$
Havzavua	259	38	$4{,}09x10^{10}$	$1{,}7x10^{9}$
Alasha	285	50	$7{,}48x10^{10}$	$3{,}1x10^{9}$
Total	7731	-	$2{,}56x10^{12}$	$10{,}7x10^{10}$

Thermal waters widely spread in the research area have scientific and practical importance for the use in agriculture and many fields of industry. Unfortunately, nowadays, except for a few primitive cases, it has not been possible to use these waters widely.

III. Results

As a result of the tectonic movements in Talish area, the uplifts, faults, horses and disjunctive dislocations played a major role in the formation of mineral-thermal water deposits.

Mineral waters are widespread in the mountainous Talish area. Mineral waters are dominated by N_2 and CH_4 gases. In addition, CO_2, He, Ar and other gases are also found. Also, the composition of the waters is rich in minerals. These mineral water deposits are considered important for treatment.

Thermal waters are widespread in Talish territory. So, the temperature of these thermal waters reaches up to 65 ^0C. It is believed that if deeper wells are drilled, the temperature may be even higher.

The relatively widespread distribution of thermal waters in the Talish zone can be used as a renewable energy source in our modern times, taking into account its high thermal energy capacity.

Abstract

The risk of exhausting the oil and gas resources used by the countries of the world for many years is increasing over time. Also, considering that the oil and gas sector is one of the main causes of climate change, it is necessary to move away from this type of fuel. In this case, there is a need to use alternative and renewable energy sources in the world. Addressing climate change requires a shift away from fuels such as hydrocarbons to renewable energy sources such as solar, wind, hydro and geothermal. Renewable energy sources are carbon-free and produce fewer emissions, making them an important component in reducing greenhouse gas emissions. Overall, the transition to renewable energy sources is critical to addressing climate change and ensuring a sustainable future for the planet. The favorable geographical position and climatic conditions of the Azerbaijani part of the Lesser Caucasus allow the wide use of ecologically clean alternative (renewable) energy sources. The article describes the perspective of using the thermal water deposits in the Azerbaijani part of the Lesser Caucasus as an alternative energy source. The analysis of fund and printed materials on thermal water deposits of the research area shows that the energy resources collected in this area can be considered as alternative energy and are of great importance for the future economy of the region. Studies show that the water temperature is high in the zones where the tectonic faults spread directly. As you move away from these zones, the water temperature decreases and the zones without lavas are characterized by natural outlets of cold mineral waters. Mineral water resources are also considered useful for the development of balneological, sanatorium-health complexes.

Keywords: geothermal, percent of mineralization, natural hazards, climate change, renewable energy

I. İntroduction

The Azerbaijani part of the Lesser Caucasus occupies the territory between the Kura in the northeast and the Araks rivers in the southeast and borders with the Republic of Armenia in the southwest.

The rift consists of separate blocks bounded by micro- and macro-tectonic faults with a very complex geological-tectonic structure, mineral and thermal water deposits are widespread on the micro-macro-tectonic faults at the contacts of separate rock masses [1]. There are numerous natural outlets of mineral and thermal water deposits in carbonate sandstones and clayey rocks, which are products of intrusive and effusive magmatism and have a special layering structure. For example, river valleys and terraces with complex structure, different formation features and ancient geological development history have caused the formation of fault and fault lines that have caused the fragmentation of separate geological blocks along the Lesser Caucasus megaanticlinorium. Carbon dioxide, hydrocarbonate, chloride-hydrocarbonate-sodium type sediments are found in the Devonian, Upper Jurassic (Oxford-Kimmerian-Tithonian), Upper Cretaceous (Campanian-Maastrichtian) and Paleogene (Middle Eocene) sediments in the central part of the Lesser Caucasus, especially in the area of Nakhchivan MR, where thick carbonate rocks are accumulated mineral waters are widespread [2] (Fig. 1).

As a whole, Quaternary lavas are characterized by high-temperature thermal waters. Studies show that the water temperature is high in the zones where the tectonic faults spread directly. As you move away from these zones, the water temperature decreases and the zones without lavas are characterized by natural outlets of cold mineral waters. For example, the total discharge of natural thermal water outlets in Yukhari Istisu, Ashagi Istisu, Bagirsag and Tutkhun areas in Kalbajar region, which is characterized by volcanic eruptions that occurred in Paleogene-Neogene (Upper Eocene and Miocene) Pliocene and Anthropogenic periods in the Lesser Caucasus, is more than 100 m^3/day [3]. The consumption of individual wells dug here at a depth of 300-400 m was 300-1000 m^3/day (temperature 28-700C). It is estimated that there is a great possibility of obtaining thermal water with a temperature of 100^{0}C through wells with a depth of 900-1000 in these areas.

A very famous sanatorium-health complex operated during the USSR in an area rich in Istisu springs in Kalbajar region. This field is considered analogous to Karlovy Vary in Czech Republic.

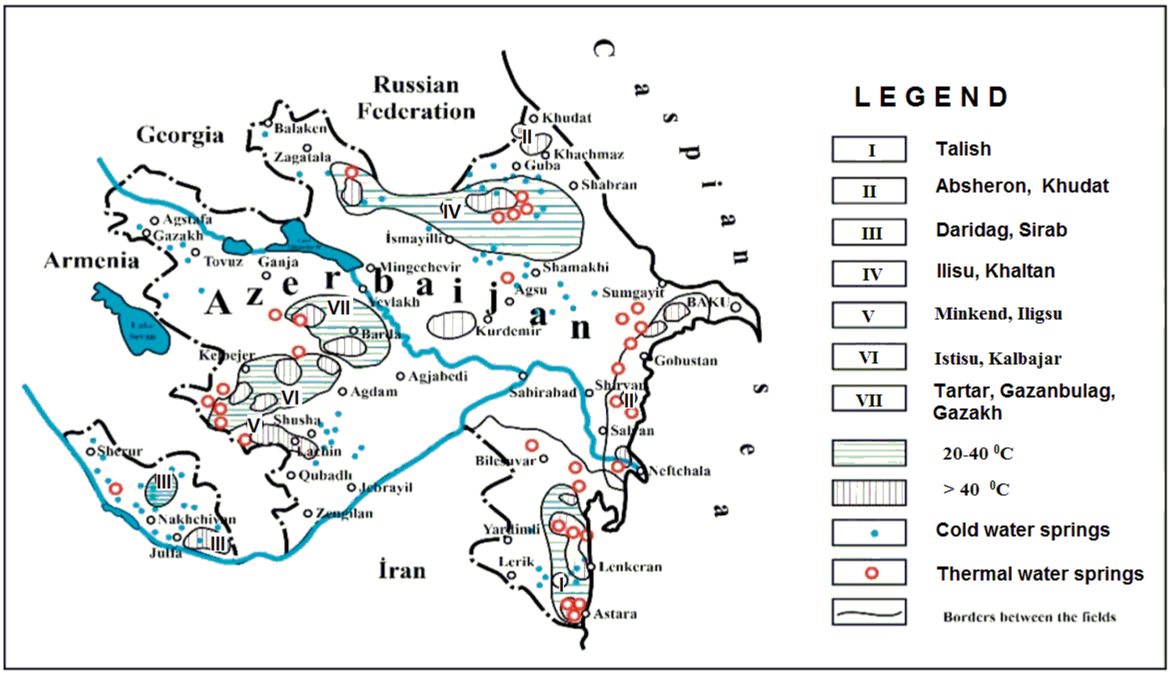

Figure 1: *Mineral-thermal waters map of Azerbaijan*

II. Methods

The amount of mineral salts contained in the mineral and thermal water deposits distributed throughout the territory of the Lesser Caucasus is much higher than that of ordinary drinking water, and these waters are rich in active chemical and specific components and gases (Table 1).

Carbon dioxide waters have great industrial and economic importance. In the territory of Azerbaijan, these waters are widespread only in the regions of the Lesser Caucasus mountain ranges and in the territory of Nakhchivan AR (Nakhajir, Istisu, Badamli, Turshsu, Daridag, etc.).

Along with Istisu and Tutkhun deposits, the Minkend-Ahmadli and Turshsu-Shirlan hydrochemical zones were studied in Kalbajar region (Fig. 2).

Table 1: *Some indicators of the main mineral and thermal water deposits distributed in the Kalbajar fold area of the Lesser Caucasus*

Name of field	Degree of mineralization, g/l	The formula of the ionic composition	Specific components	Water temperature, ^0C	pH	Consumption, 10^3 l/day

Since the mineral water group of the intestinal area comes out through the granitoids, their contents are enriched with radium element, and their radioactivity gradually decreases as they move away from the dykes [4].

The above-mentioned Tutkhun mineral water field is characterized by a large amount of carbon dioxide mineral water outlets in the Tutkhun river valley (Gotursu, Garasu, Mozchay, Galatalig, Zulfugarli, Oruclu water groups) [5,6,7].

In general, in this zone, the Cenomanian tuffogenic-clastic rocks, characterized by conglomerate and tuffaceous sandstones, are considered more watery. Limestones and andesites (Eocene age) with vertical cracks, which create infiltration conditions, play the main role in ensuring the hydration of these rocks [8,9,10].

Turshsu-Shirlan zone is one of the most interesting mineral water deposits in the Lesser Caucasus. These deposits were discovered in the deep valleys of Gargarchay River (Turshsu) and Khalfalichai River (Shirlan) 16 km from Shusha region. Here, as a result of the Middle Jurassic volcanogenic layer sliding over the sediments characterized by lower Cretaceous shaly sandstones and crushing them, it created conditions for the formation and movement of mineral waters.

Figure 2: *Mineral-thermal water outlet in Kalbajar*

The mineral water deposits distributed in the Nakhchivan fold area of the Lesser Caucasus are divided into hydrochemical zones along 3 lines.

A number of mineral water deposits (Badamli, Vaykhir, Sirab, etc.) were studied along the 1st line. Badamli and Sirab mineral water sources are closely related to rocks characterized by Upper Cretaceous, Paleocene and Eocene age marls, sandstones, conglomerates, andesite and their tuffs and tufobreccias. The chemical composition of mineral waters is hydrocarbonate-chlorine-sodium.

The 2nd line of mineral waters of the territory passes through the border zone with Armenia in the southwest direction of Nakhchivan. In this zone, there is a zone of tectonic tension accompanied by fractures, cracks and disjunctive dislocations.

The 3rd line of mineral water sources of the area passes through Daridag water sources. These water sources are collected in a large anticlinal fold zone extending in the northwest direction in connection with the Upper Cretaceous and Eocene marly-sandstone rocks. The mineral waters of this zone are chlorinated-hydrocarbonate-sodium based on their chemical composition.

In total, there are more than 200 natural mineral water springs in the area of Nakhchivan folds. The mineral water deposits of this area resemble a hydrochemical museum with their diversity (Table 2).

When the mineral waters of the Lesser Caucasus come to the surface, they form many sediments in various forms (argonite, stalatite, stamite, etc.). For example, argonites formed in the area of Sirab village in Babak district of Nakhchivan are used as an excellent type of marble.

"Daridag" mineral water deposits in Julfa region are used to buy CO_2.

There are 2 types of mineral water in the "Sirab" mineral water field:

1. "Barjomi" type waters; operational reserve is more than 200000 l/day.
2. "Narzan" type waters; operational reserve is more than 500000 l/day.

Table 2: *Some indicators of natural water outlets of the main mineral and thermal water deposits distributed in the Nakhchivan fold area of the Lesser Caucasus*

Name of field	Gas composition	Degree of mineralization, g/l	The formula of the ionic composition	Specific components	Water T, ^0C	pH	Consumption, 10^3 l/day
Shakhtakhti	H_2S	2,8	$\frac{SO_4 67(HCO_3 10)}{Ca58Na30}$	H_2S+HS	21,0	6,2	70

In the Ordubad region of Nakhchivan, the Ordubad-Araz hydrochemical zone passes along the axis of the anticlinal uplift, around the fault zone and through the outer part of the intrusive.

The main mineral water deposits are:

1. The natural mineral water outlet in the Dasta area comes out of the gravel and gravel sediments on the ground. These waters belong to the Narzan type, the chemical composition belongs to the hydrocarbonate-sulfate-calcium type. Water discharge is 5000 l/day, water temperature is 19 ^{0}C, mineralization rate is 1.4 g/l, carbon dioxide (CO_2). Among the specific components – Ni, Pb, Zn were determined in the water. An exploratory exploitation well with a depth of 395 m was dug in this area. Mineral water-bearing rocks consist of fissured sandstones. The flow rate of the well is 300000 l/water, the degree of mineralization is 18.2 g/l, the chemical composition is chlorinated-hydrocarbonate-sodium, Fe (iron) and Br (bromine) have been determined in the water as specific components.

2. The Nasirvaz area spring emerges from small-grained Cognac-Sectonian sandstones. The discharge of the spring is 350,000 l/day, the degree of mineralization is 1.5 g/l, the water temperature is 14.3 0C, specific components Ni and Fe are determined in its content, it is carbon dioxide.

3. The Ketam area has a natural mineral water outlet, which comes out of the Cretaceous sandy-marly, calcareous sediments. The flow rate of the water is 250 thousand l/day, the degree of mineralization is 1.9 g/l, the chemical composition of the water is hydrocarbonate-sulfate-calcium, it contains Cu, Ni.

4. The Tivi area consists of an alternation of chalky marly, sandy, and limestone rocks. The flow of water is 200,000 l/day, the temperature is 100C, it belongs to carbon dioxide, hydrocarbonate-sulphate-calcium type.

5. Paraga emerges from the delluvial sediments to the earth's surface. Water discharge is 120 thousand l/day, mineralization rate is 1.7 g/l, water temperature is 16.5 ^{0}C. It contains specific components such as nickel, copper, and bromine. The chemical composition is sulfate-hydrocarbonate-calcium.

6. The flow of water in Alyagi area is 80000 l/day, it comes from delluvial sediments, the degree of mineralization of water is 3.6 g/l, the temperature is 19.5^{0}C with carbon dioxide, and the chemical composition belongs to the hydrocarbonate-sulfate-sodium type. Specific components of water include iron and bromine.

7. The flow of water in the Belav area is 40 thousand l/day, the temperature is 18.5 ^{0}C, the degree of mineralization is 2 g/l, and the chemical composition belongs to the hydrocarbonate-sulfate-sodium type. Among the specific components, water contains copper, bromine, iodine and carbon dioxide.

8. Bist area - delluvial sediments, water discharge 25 thousand l/day, water temperature 180C, mineralization rate 3.9 g/l, chemical composition belongs to hydrocarbonate-sulfate-calcium type. Carbon is gaseous, it contains copper, bromine and iodine as specific components.

9. Specimen area - delluvial sediments, water discharge 10 thousand l/water, mineralization rate 0.8 g/l, refers to carbon dioxide, hydrocarbonate-sulphate-calcium waters. Specific components of water include nickel, copper, and bromine.

10. Geyenza area - delluvial sediments, water discharge 12 thousand l/day, mineralization rate 5.6 g/l, carbon dioxide, water temperature 15 ^{0}C. Specific components of water include nickel and bromine.

III. Results

During the long geological period, mountain folding of the Lesser Caucasus, which continued with varying intensity in connection with the Alpine folding in the Caucasus, occupied a large area and participated in the formation of geochemical and geothermal characteristics of the geostructural zones on the right bank of the Kura basin. The Lesser Caucasus mega-anticlinorium has complex geological-tectonic conditions characterized by alternation of carbonate, sandstone and clayey rocks and tectonic faults, which are products of intrusive and effusive magmatism.

Analysis of geological materials shows that carbonic acid (H_2CO_3) acts on layers above magma, turning them into carbonate rocks. Free sulfuric acid is formed when sulfides, especially pyrite, are oxidized. That acid chemically reacts with limestone and other rocks to convert carbonates into sulfates. Carbon dioxide (CO_2) is compressed and remains free, and in some cases dissolved in water.

Due to the constant interaction with the mountain rocks in the research object, the degree of mineralization of the waters increases as a result of the dissolution of the rocks and the reaction of individual particles. The degree of mineralization is formed depending on the lithological composition of the rocks, the temperature and pressure of the substance in which the water moves.

Effective use of mineral and thermal water deposits of the Lesser Caucasus has been highly appreciated, especially in the Istisu, Tutkhun, Minkend, Ahmadli hydrothermal zones, according to the results of the search and exploration works conducted in these regions. The temperature of thermal waters in these zones is 54-74 ^{0}C, the total mineralization rate ranges from 4.2-7.9 g/l, and their chemical composition belongs to the hydrocarbonate-chlorine-sulfate type.

Abstract

The article examines the impact of the printing industry on environmental pollution. It was determined that the environmental problem is particularly relevant in this industry due to the high concentration of printing facilities in residential areas. The printing industry releases various harmful substances into the environment. Pollutants entering the atmosphere and wastewater entering the soil and groundwater are dangerous for humans, animals and plants. In the printing process, the printing ink breaks down, which causes the effect of ink dusting. This paper proposes a method to determine the amount of ink involved in dusting, taking into account the surface roughness of the printing plate. For this purpose, profilograms of the surface roughness of the printing form were taken. It was determined that an increase in the surface roughness of the printing form leads to an increase in the amount of ink involved in the dusting process, which, according to the results of theoretical studies, is 16.6% of the total amount of ink applied to the printing form. the surface of the printing form. It was also determined that the variation scheme of the amount of ink involved in the formation of dust in all sections of the printing machine is the same. The amount of paint involved in the formation of dust also increases many times with the increase in circulation. In order to experimentally confirm the theoretical results, the amount of ink applied to the surface of the printing plate was determined by the gravimetric method and the amount of ink involved in the formation of dust was calculated. The obtained results can be important information to ensure the cleanliness of the environment. The proposed method for determining the amount of ink involved in dust formation may be useful for professionals dealing with environmental problems in the printing industry. Also, the results of calculations can be used to solve environmental problems.

Keywords: Printing industry, pollutants, paint dusting, offset printing, roughness

I. Introduction

In recent years, climate change on our planet has worried society more. Environmental pollution has become one of the most urgent global problems. The current environmental situation has led to an increase in the interest of state institutions in the issues of environmental cleanliness. Government agencies, in turn, are tightening the requirements for the industry. Energy-saving technologies have become the highest priority in society, along with environmentally friendly products. With the use of these technologies, the complete disposal or recycling of production waste has become possible.

Consider the printing industry in terms of its impact on environmental pollution. Polygraphy is one of the most developed fields. It is characterized by a high concentration in residential areas, which makes its impact on the environment more noticeable. Therefore, the issue of ecology is particularly relevant in this industry. At present, printing houses are spreading in any country in a chaotic manner and without considering environmental safety. Modern printers produce many different products: packaging, labels, books, magazines and promotions. Typically, this industry is dominated by small businesses [1, 2]. Often, its representatives are focused on making a profit. Entrepreneurs are rarely interested in the environmental damage caused to the environment by their production. Some works [3, 4, 5] noted that the printing industry emits a relatively small amount of harmful substances into the environment. However, pollutants entering the atmosphere and wastewater entering the soil and groundwater are very dangerous for people, animals and plants. It is also necessary to take into account that most printing enterprises are located within the city limits, in residential areas and there are virtually no sanitary protection zones in them. Environmental protection at these enterprises is a necessary and important problem. Also, one of the important factors in printing is energy consumption. Printing makes a significant contribution to air pollution and the consumption of non-renewable energy sources. Improving technological processes in this direction is considered the most promising way to solve the problem of environmental protection.

Each printed publication goes through three stages of the printing process during its production: prepress preparation, printing and postpress finishing works. To fully understand the impact of printing on environmental pollution, each stage should be considered separately.

The work [4] shows that the pre-press stage does not have a negative impact on the environment, as the amount of technical waste is minimized.

This work also shows that post-printing processes do not have a significant impact on the environment. The analysis of the study shows that most of the emissions that have a negative impact on the environment are created directly during the printing process. According to Makarov [3], the main environmental threat of printed products is related to the printed material, as it constitutes more than 90% of the mass of the entire product. Currently, there is no clear vision of environmental problems in the printing and publishing industry. There is also no unified development program and proper management. Printing production was traditionally considered harmful to the environment.

II. Ink dusting in the printing process

Humanity uses a large number of paints and varnishes. The most common of them are construction and household, occupying more than half of the entire market. According to Makarov [3] the consumption of printing varnishes and paints is much less, i.e. 1-5 grams per square meter. In other industries, the application layer is tens of times larger. However, one kilogram of printing paint contacts the environment as well as several dozen kilograms of ordinary paint.

The printing industry uses different methods of applying paints and drying them. Almost all printing houses are faced with air pollution. This is due to the use of organic solvents. However, this is not the only air pollutant. The authors of a number of works [3, 5, 6, 7] also found that high printing speeds cause dusting, which leads to additional air pollution with paint and paper particles.

As the printing ink breaks down, ink filaments are formed and individual droplets are formed due to the rapid expansion of the ink, which creates a "dusting" effect. The authors of the work [6] show that the dusting is the result of the fragmentation of paint threads into many small particles and intensive scattering of these particles into the surrounding space under the influence of centrifugal forces. There are various reasons that cause dusting of paint. As noted by the authors of the works [5, 7, 8], the level of dusting is affected by the roughness of the paint-bearing surfaces and the thickness of the paint. film, paint properties and cavitation. The proportion of dust increases at high speed and higher ink viscosity, which affects not only print quality but also health and safety.

The authors of the works [5, 7] simulated the process of transfer and splitting of printing ink at the exit from the printing contact zone, with specifically specified components of the printing system, to predict and quantify the printing ink that has transferred to ink strands and is involved in the formation of "ink dusting". In the work of Khalilov et al. [8], the influence of the mechanics of a friction printing pair on ink dusting in the printing process was studied, taking into account the roughness of the surface of the printing plate.

Thus, it can be concluded that a printing house can cause significant air pollution, and it is necessary to carry out a set of measures to reduce risks.

III. Methodology for quantitative assessment of printing ink involved in the formation of "ink dusting"

In the printing process, printing ink is transferred from the inking unit to the printing plate and from the plate to the printed material [9, 10, 11].

In offset printing, separation of the ink layer occurs in two zones of the three-cylinder printing press (Figure 1), that is, between the plate and blanket cylinders, and between the blanket and printing cylinders.

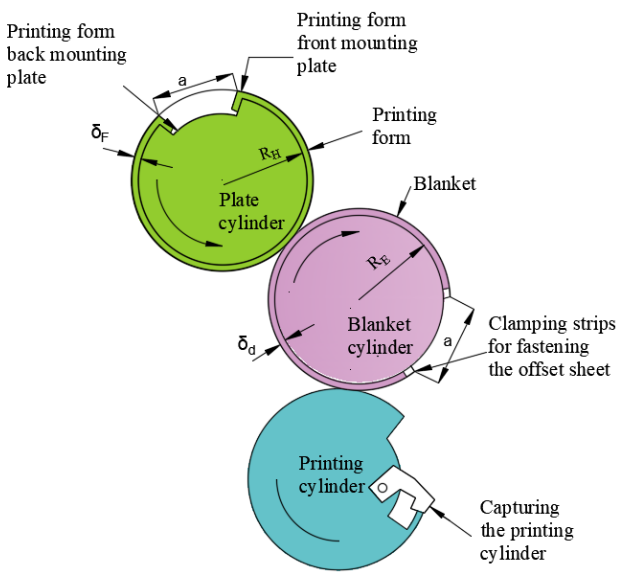

Figure 1: *Three-cylinder printing apparatus*

To standardize the offset printing process, it is necessary to select the correct printing system components [12]. According to Panichkin et al. [13], offset printing involves the transfer of a viscous incompressible fluid (ink). In the work of Aliyev [14], ink transfer to the printing plate was theoretically studied, taking into account the surface roughness of the printing plate. According to the scheme proposed by the authors of some works [14, 15], the effect of the surface roughness of the printing plate on ink separation in the indirect printing method was studied. Also, to determine the amount of ink on the printing plate on the contact strip, taking into account the microgeometry of the surface of the printing plate, the contact scheme of the printing pair (Figure 2) proposed by Khalilov et al. [8] was used.

In the work of Aliev [15], the amount of ink m on the printing form in the contact strip before printing is defined as follows

$$m = m_f + m_k \tag{1}$$

where m_f – is the amount of paint lying freely on the surface of the printing form in the contact strip, without taking into account the roughness; m_k –is the amount of paint that is in the free space of the roughness of the surface of the printing form in the contact strip

$$m_k = \frac{\rho \pi R'_H L}{180^\circ} \gamma_1 \left[\frac{R_{\max}\left(2R'_H - R_{\max}\right)}{2R'_H} - R_a \right] \tag{2}$$

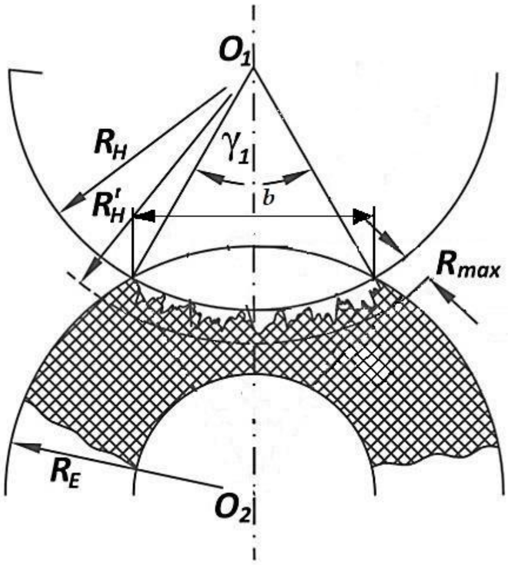

Figure 2: *Printed pair contact diagram, taking into account the surface roughness of the printing form*

Where L is the contact length along the generatrix of the contacting cylinders; R'_H – is the radius of the plate cylinder taking into account the thickness and surface roughness of the printing plate, $R'_H = R_H + \delta_F$, R_H –is the radius of the plate cylinder excluding the thickness and surface roughness of the printing plate; δ_F –is the thickness of the printing plate, taking into account the surface roughness of the printing plate; γ_1 – is the central angle of the contact zone sector; $R_{\max}$ – is the maximum height of the surface microroughness of the printing plate; R_a –is the arithmetic mean height of the surface microroughness of the printing plate; ρ –is the specific gravity of the ink;

Also, the amount of ink M_F –on the entire surface of the printing plate during one cycle of the printing machine, taking into account the roughness, before printing is determined in the following form

$$M_F = kk_1 \left\{ m_f + \frac{\rho \pi R'_H L}{180^\circ} \gamma_1 \left[\frac{R_{\max}\left(2R'_H - R_{\max}\right)}{2R'_H} - R_a \right] \right\} \tag{3}$$

Where $k-$ is the coefficient of filling the form with printing elements - for line images and text $k=0{,}13\div 0{,}15$, for raster $k=0{,}4\div 0{,}6$, for solid $k=1$ [16]; $k_1-$is the number of contact strips that can be located across the width of the nominal surface area of the printing form $k_1 = B/b$, where B is the width of the nominal area of the printing form and b is the width of the contact strip.
With a known value of the weight M of the printing form, without applying paint, M_F can be determined in the following form

$$M_F = M_1 - M \tag{4}$$

where M_1 – is the weight of the printing plate together with the applied paint before printing, taking into account the roughness. The values of M and M_1 can be determined gravimetrically.

When the paint layer is separated, the printing paint also splits and dusts. To determine the total amount of paint that has passed to dusting M_d in the contact strip, for one printing section, we write the following expression

$$M_d = M_{d1} + M_{d2} \tag{5}$$

where $M_{d1}-$ is the amount of paint transferred to dusting in the contact strip between the plate and blanket cylinders; M_{d2} – is the amount of paint transferred to dusting in the contact strip between the blanket and printing cylinders.

According to the results of the research by the authors of the work [17], it was found that after the separation of the ink layer, its thickness on the blanket cylinder of the printing apparatus is estimated at up to 38% of the total amount of paint applied to the printing form. This differs significantly from the results of similar studies, in which the division of the ink layer between the cylinders is usually estimated at 50%. Based on this, for one cycle of the printing machine, the expression can be written

$$M_{D1} = 0.5M_F - M_b \tag{6}$$

where M_{D1} – is the amount of paint transferred to dusting for one printing machine cycle between the plate and blanket cylinders; M_b – is the amount of paint lying on the blanket surface after contact between the plate and blanket cylinders after one cycle.
Similarly, the following expression can be written

$$M_{D2} = 0.5M_b - M_p \tag{7}$$

where M_{D2} – is the amount of paint transferred to dusting for one printing machine cycle between the blanket and printing cylinders; M_p is the amount of paint lying on the surface of the substrate after contact between the blanket and printing cylinders.

Taking into account the above information, the following expressions can also be written

$$M_b = 0.38M_F \tag{8}$$

$$M_p = 0.38M_b \tag{9}$$

Taking into account (8), we write formula (9) in the form

$$M_p = 0.144 M_F \tag{10}$$

Substituting values (8) and (10), we write expressions (6) and (7) in the following form

$$M_{D1} = 0.5M_F - 0.38M_F = 0.12M_F \tag{11}$$

$$M_{D2} = 0.19M_F - 0.144M_F = 0.046M_F \tag{12}$$

Taking into account formulas (4), (11) and (12), we write formula (5) for one cycle of the printing machine in the form

$$M_D = 0.166(M_1 - M) \tag{13}$$

Based on expression (13), we can conclude that the amount of paint transferred to dusting as a percentage is 16.6% of the total amount of M_F paint on the entire surface of the printing form. Considering that in multi-color printing, the printing machine has several printing sections, their number is equal to $i = 1, 2, .., N_S$, and the number of printing cycles of the machine is equal to circulation. N_T (print circulation), we write formula (13) in the following form:

$$M_{DT} = N_T \sum_{i=1}^{N_S} (M_D)_i \tag{14}$$

where M_{DT} – is the total amount of paint transferred to dust during the printing of the entire print run.

IV. Research results

For the study, the Rapida KBA 105 offset printing machine (Germany) was selected, which has $N_s = 4$ printing sections, with a form cylinder radius $R_H = 0.1494m$ and a blanket cylinder radius $R_E = 0.1468m$. A rubber-fabric blanket with a thickness of $0.95mm \pm 0.01mm$ was selected. A metal (aluminum) printing form of the PRO-V brand from Fujifilm (Japan) with a thickness of $\delta_F = 0.3mm$ was also selected. The contact length of the cylinders *L=0.104 m.*. The density of the printing ink used in the experiment is $-\rho = 1800\, kg/m^3$. When calculating the amount of ink, the surface roughness parameters of the printing plate were determined for each printing unit used in the studies. To determine the roughness parameters, surface profilograms of these printing plates were taken using a model 130 profilometer. A sample profilogram is shown in Figure 3.

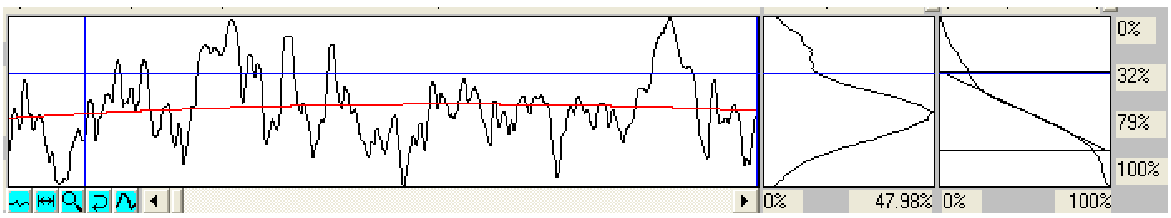

Figure 3: *Profilogram of the printing plate surface roughness*

During the study, these printing plates were installed in the cyan (C), magenta (M), yellow (Y) and black (K) printing units of the Rapida KBA 105 machine. The roughness parameters for each plate from the profilograms were determined as follows:

1. (C) $R_{\max} = 2.5\mu m$; $R_a = 0.396\mu m$

2. (M) $R_{\max} = 1.03\mu m$; $R_{\max} = 1.03\mu m$
3. (Y) $R_{\max} = 1.85\mu m$; $R_{\max} = 0.375\mu m$
4. (K) $R_{\max} = 0.644\mu m$; $R_{\max} = 0.0615\mu m$

The amount of paint on the printing form was determined by the gravimetric method. The mass of the printing form was weighed before and after rolling the paint onto the surface of the printing form. After that, the difference in the masses of the printing form before and after rolling the paint onto the surface of the printing form was calculated. To determine the masses, analytical electronic scales of the KERN FTB 3Ko.1 model were used. The experimental data of gravimetric measurements and the results of calculations for raster images $(k = 0.5)$, at $k_1 = 224$ for one cycle of the Rapida KBA 105 printing machine are given in Table 1. It was found that an increase in the roughness of the surface of the printing form leads to an increase in the amount of paint on the printing form, which contributes to an increase in the amount of paint participating in dusting.

Table 1: *Experimental data of gravimetric measurements and calculation results for printing sections for one cycle of the Rapida KBA 105 machine*

№	Printing plate in matching color	Experimentally determined weight of the printing form without applying paint	Experimentally determined weight of a printing plate with ink applied	Maximum height of surface roughness of the printing form	The arithmetic mean height of the surface roughness of the printing form	The amount of ink on the surface of the printing plate	The amount of paint involved in dusting

V. The discussion of the results

To determine the amount of paint M_D, involved in dust formation during the printing process, the effect of the printing plate surface roughness on paint dusting was investigated. The amount of paint M_D, involved in dusting was theoretically calculated and found to be 16.6% of the total amount of paint M_F, applied to the surface of the printing plate. To experimentally confirm the theoretical results, the amount of paint applied to the surface of the printing plate was determined by the gravimetric method. Using the data obtained, the amount of paint involved in dusting was calculated, which is an important factor for ensuring a clean environment. The experimental results show that the change in the amount of paint involved in dusting depends on the surface roughness of the printing plate. Since at the maximum roughness height $R_{\max} = 0.644\mu$m the amount of paint involved in dust formation for one machine cycle in the cyan (C) color section is $M_D = 0.015g$. And at $R_{\max} = 2.5\mu$m in the magenta (M) color section this value increases to $M_D = 0.035g$. (Table 1.) Corresponding changes are also observed in the yellow (Y) and black (K) color sections of the printing machine.

Fig. 4 shows the dependence of the amount of M_D, ink involved in the dusting process on N_T by printing sections corresponding to the cyan (C), magenta (M), yellow (Y) and black (K) colors of N_T . Rapida KBA 105 machine From the graphs shown in Figure 4, it is clear that the scheme of change of the amount of paint involved in the formation of dust is the same in all sections.

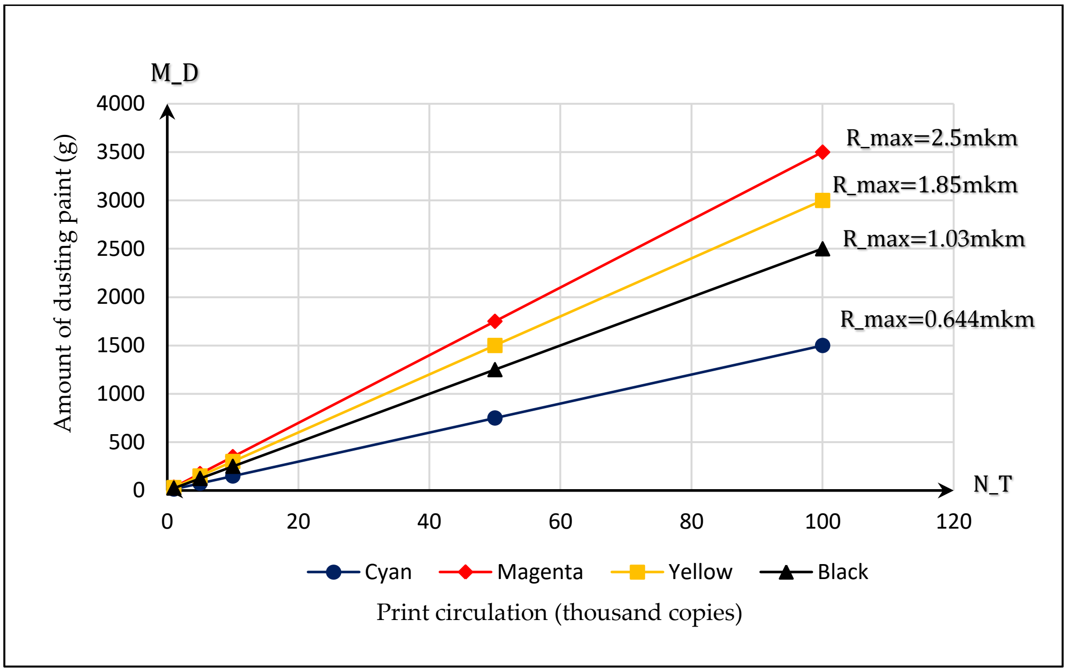

Figure 4: *Dependences of the amount of M_D paint involved in dusting on the print run N_T, by printing sections of the corresponding colors of the Rapida KBA 105 machine*

With an increase in the print run, a several-fold increase in the amount of paint involved in dust formation is observed. As an example, calculations were made for print runs from 1,000 copies to 100,000 copies of prints. Since for the cyan (C) section with a print run of 1,000 copies, the amount of paint involved in dust formation was $M_{DT} = 15g$,and with an increase in the print run to 100,000 copies, the amount of paint involved in dust formation reached $M_{DT} = 1500g$. Also, for the magenta (M) section, these values were similarly $M_{DT} = 35g$ and $M_{DT} = 3500g$. Similar changes in the increase in the amount of paint involved in dust formation, when printing the corresponding print runs, are also observed in the yellow (Y) and black (K) sections of the printing machine (Figure 4.). It has been established that the obtained difference in the amount of paint involved in dust formation during printing of the corresponding print runs depends on the roughness of the surface of the printing form. Since an increase in the roughness of the surface of the printing form leads to an increase in the amount of paint involved in dust formation. Also, with an increase in the print run, a multiple increase in the amount of paint involved in dust formation is observed.

The graph of the dependence of the total amount of M_{DT} paint involved in dusting on the print run N_T for all sections of the printing machine is shown in Figure 5.

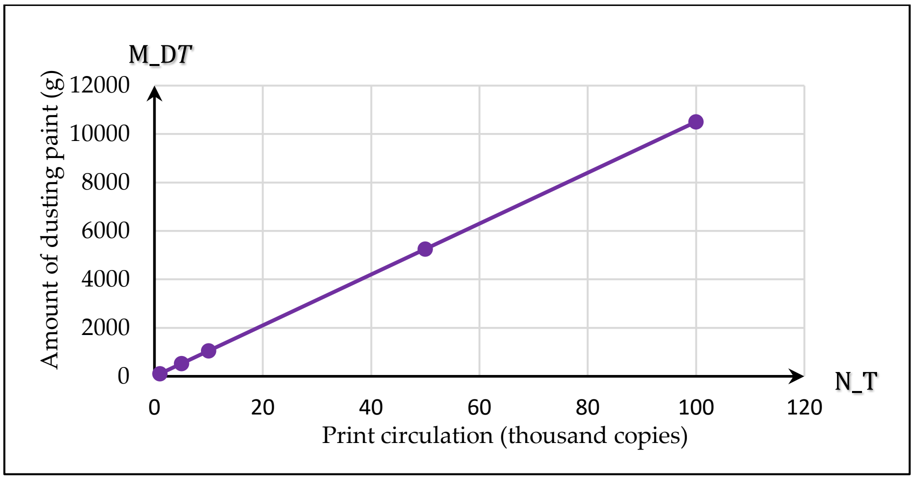

Figure 5: *Dependence of the total amount of* M_{DT} *paint involved in pollination on the print run* N_T

The graph shows that with an increase in the N_T circulation from 1,000 copies to 100,000 copies, the total amount of paint involved in dust formation during the printing process increases from $M_{DT} = 105g$ to $M_{DT} = 10500g$, which leads to environmental pollution. Based on the results of the studies, it can be concluded that when designing printing processes, it is necessary to take into account the amount of paint involved in dust formation, which pollutes the environment and significantly affects the quality of the products. The advantages of this study in comparison with analogues are the following: for the first time, the amount of paint involved in dust formation during the printing process is determined as a percentage of the total amount of paint applied to the surface of the printing plate. Also, knowing the geometric characteristics of the surface of the printing plate, it is possible to determine the amount of paint polluting the environment, which is very important in solving environmental problems. Therefore, before the printing process begins, it is recommended to select printing forms with optimal values of surface roughness parameters.

This method for determining the amount of paint involved in dust formation can be useful for specialists dealing with environmental issues in the printing industry.

Abstract

This technological development is aimed at using renewable energy sources to provide electricity to oil wells on the Apsheron Peninsula, which contributes to improving the environmental situation and justifying the economic efficiency of this approach. The technology for producing green energy from polluted lakes on the Apsheron Peninsula has enormous potential for solving two main problems: environmental pollution and energy shortage. This project represents an innovative approach to utilizing polluted water resources, combining it with electricity production to support the energy needs of oil wells and the population.

Keywords: hydrogen production, electricity, renewable energy sources, water electrolysis, thermal power station, sustainable energy solution

I. Introduction

The Apsheron Peninsula, located on the shores of the Caspian Sea, is one of the key regions of Azerbaijan. It is rich in natural resources, including lakes and water bodies, which play an important role in the region's ecosystem. However, in recent decades, due to various anthropogenic and natural factors, many of these water bodies have become polluted, posing a serious threat to both the environment and the health of local residents [1-3].

One of the key challenges facing the region is not only the cleaning of polluted water bodies but also the use of their potential for green energy production. In this context, the technology for producing green energy from polluted lakes on the Apsheron Peninsula represents an important and promising direction for development.

The aim of this work is to study and analyze the possibility of using technology for producing green energy based on the purification of polluted lakes on the Apsheron Peninsula to achieve ecological and economic benefits. Within the framework of this work, the main aspects of the technology, its potential in the context of the region, as well as the ecological and economic benefits that can be obtained through its implementation will be considered [4-6].

This study is not only important in terms of improving the region's ecology but also has the potential to stimulate economic development through the creation of new jobs, increasing investments in infrastructure, and reducing dependence on traditional energy sources [7; 8].

II. Methods

Key aspects of this technology:

- Installation of wind turbines on the surface of polluted lakes: wind turbines will be placed on the surface of polluted lakes to harness wind energy for electricity production. This is an efficient way of utilizing available natural resources for generating clean energy.

- Hydrogen production: using electrolysis powered by the electricity generated from wind turbines, hydrogen will be produced. This process involves splitting water into hydrogen and oxygen, with hydrogen being utilized as a green fuel.

- Provision for oil wells: hydrogen can be used as a clean energy source to power oil wells, reducing dependence on traditional energy sources such as oil or natural gas, and decreasing emissions of greenhouse gases and other harmful substances.

- Providing energy to the population: the generated electricity and hydrogen can be used to meet the energy needs of the population in nearby areas, contributing to improving the quality of life and reducing environmental pollution from oil operations.

Thus, this technology represents an integrated approach to addressing multiple issues simultaneously, including energy security, reducing environmental pollution, and supporting the oil industry.

Overall, the technology for producing green energy from polluted lakes on the Apsheron Peninsula presents an effective and sustainable solution for reducing environmental pollution and providing a sustainable energy source for the region.

1. Investigation of Polluted Lakes on the Apsheron Peninsula

An analysis is conducted to identify contamination with oil products. Water samples are collected, then gas chromatography-mass spectrometry (GC-MS) is used to determine the types and concentrations of hydrocarbons in the water. Additionally, analysis of heavy metals is performed using atomic absorption spectrometry (AAS) [9].

For the chemical analysis of the polluted water bodies of "Boyuk Shor" on the Apsheron Peninsula, various apparatuses and methods were used depending on the specific analysis objectives and types of pollutants. The table below includes the main stages of analysis, equipment, and methods employed: 12 water sample bottles were collected from 12 different local sites and depths of Lake "Boyuk Shor."The results of the chemical analysis of the polluted waters of "Boyuk Shor" indicate significant contamination of water bodies on the Apsheron Peninsula with heavy metals, especially lead (Table 1).

Problems with the presence of oil products and coliform bacteria are also identified, posing a risk to public health. Urgent measures are needed to reduce emissions of pollutants and restore water quality in the region.

Despite the identified contamination of water bodies on the Apsheron Peninsula with heavy metals, oil products, and the presence of coliform bacteria, hydrogen in this context can be identified as a potential resource that can be used for clean and sustainable energy [10].

The specific gravity of lead (Pb) is 11.34 g/cm^3, mercury (Hg) is 13.55 g/cm^3, and cadmium (Cd) is 8.65 g/cm^3. The specific gravity of these metals is significantly higher than that of water, and they are concentrated at the bottom, with the rest located in the upper layer. Based on our measurements, the average depth of the lake in different locations is about 5 meters, so considering the presence of heavy metals in the bottom layer of the lake and other lighter impurities in the upper layer, the analysis should be taken at a depth of 2.5 meters using filters for electrolysis.

Table 1: *Results of the analysis of water pollution in "Boyuk Shor" of the Apsheron Peninsula*

2. Renewable Energy Sources

The Apsheron Peninsula in Azerbaijan has the potential to utilize several renewable energy sources. Some of these include: wind energy, solar energy, hydro energy, geothermal energy, biomass.

Each of these sources has its advantages and limitations, and a combination of various renewable sources can ensure sustainable and efficient energy production on the Apsheron Peninsula.

In the case of wind turbines on the Apsheron Peninsula, the height of installation plays a critical role in determining their effectiveness. It is important to place wind turbines at a sufficient height to ensure maximum capture of wind flow with minimal turbulent effects (Fig.1) [11-13].

The power of the power station depends on several factors, including the quantity and characteristics of the installed wind turbines, the efficiency of the electrolysis system for hydrogen production, and the overall electricity demand for oil wells. Let's assume several parameters to specify the answer.

Wind turbine power: according to our calculation, it is necessary to install a wind power station with wind turbines of 2 megawatts (MW) each. With the installation of 5 wind generators, the total required power will be 10 MW.

Electrolysis power: assuming an electrolyzer with an efficiency of 80%, meaning 80% of the wind turbine's electricity is used for hydrogen production. In this case, the electrolysis power will be 0.8 * 10 MW = 8 MW.

Hydrogen power station capacity: if hydrogen is used in hydrogen fuel cells with an efficiency of 60%, the hydrogen power station capacity will be 0.6 * 8 MW = 4.8 MW. Thus, in this scenario, the total power of the power station, including the wind farm, electrolysis system, and hydrogen power station, will be approximately 4.8 MW. Let's conduct a comprehensive analysis of the economic and environmental efficiency for the proposed project, which includes the use of electrolysis for hydrogen production and the purification of polluted water bodies on the

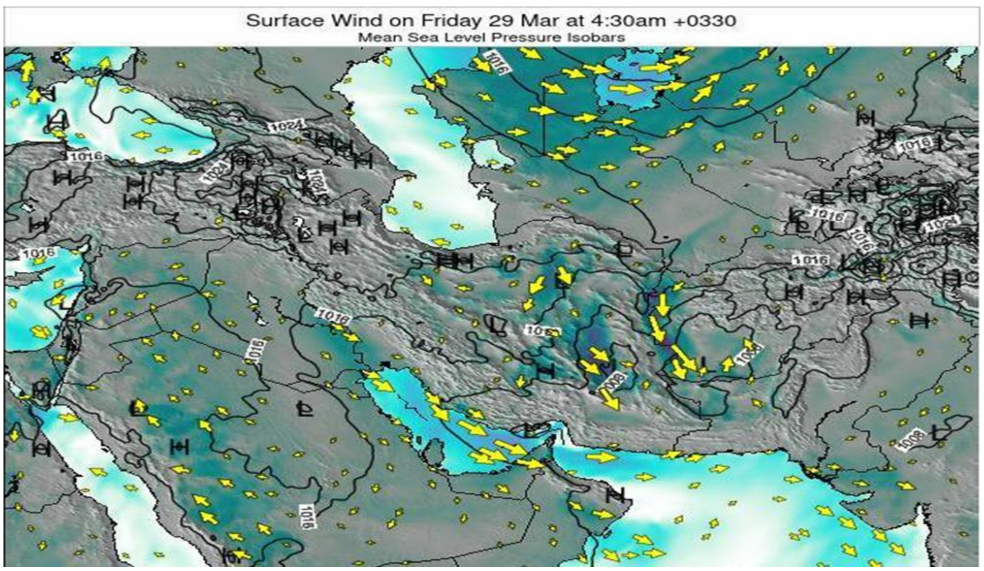

Figure 1: *Wind Map of Azerbaijan*

3. Energy Efficiency and Energy Consumption of Water Electrolysis Apsheron Peninsula.

Water electrolysis is a process in which water is decomposed into oxygen and hydrogen using an electric current passing through an electrolyte. There are several different types of water electrolysis, including alkaline (potassium-sodium) electrolysis, acidic electrolysis, variable electrolysis, and photoelectrolysis [14;15].

The energy efficiency and energy consumption of water electrolysis depend on several factors, including the technology used, operating conditions, and the efficiency of the electricity source. Here are the key aspects: There are several methods of water electrolysis, such as alkaline electrolysis (Fig. 2), PEM (polymer electrolyte membrane) electrolysis (Fig. 3), and high-temperature electrolysis (Fig. 4). Each has its energy consumption characteristics. For example, PEM electrolysis is typically more energy-efficient compared to alkaline electrolysis [16].

4. Electrolysis Technology

The hydrogen production processes discussed in this article are processes where water is the only input material, and hydrogen and oxygen are the only output materials. Moreover, the required energy expenditure should mainly consist of heat rather than useful work, such as electricity. As mentioned above, these processes can be represented as a series of chemical reactions summing up the decomposition of water [17].

Hydrogen production through water electrolysis is one of the most promising methods for obtaining "green" hydrogen that does not produce greenhouse gases when used. However, as noted, the high energy consumption of this process is a serious concern.

Advantages of Different Methods: The advantages of various methods depends on production conditions, raw material availability, energy costs, and environmental considerations. The development and diversity of hydrogen production methods play a crucial role in providing a sustainable and environmentally friendly energy source for the future [18].
In Azerbaijan, the development of these hydrogen production methods will depend on specific production conditions: raw material availability, energy costs, and environmental characteristics. Let's consider several methods of hydrogen production and their potential benefits for Azerbaijan: steam methane reforming (SMR), water electrolysis, thermochemical water splitting, and photocatalytic water splitting.

Water Electrolysis: If Azerbaijan has available renewable energy sources such as solar or wind, water electrolysis can be an effective and environmentally friendly method of hydrogen production. This may be particularly relevant in areas where there is potential for deploying renewable energy sources.

The use of platinum coating on a steel electrode can increase the efficiency of water electrolysis. Platinum is a well-known catalyst for water electrolysis, as it possesses high catalytic activity and corrosion resistance in aggressive electrolysis conditions.

Steel can be an inexpensive and sturdy material for electrodes. However, without a catalyst like platinum, water electrolysis may require higher voltage for an efficient process. Coating the steel electrode with a thin layer of platinum can significantly reduce this potential and provide more efficient water electrolysis.

However, it is worth noting that the use of platinum can make the process more expensive due to the high cost of this precious metal. In this regard, researchers are working on finding more affordable and efficient catalysts for water electrolysis.

Therefore, the use of nanostructured catalysts, such as metal nanoparticles or their compounds, can increase activity and enhance catalyst efficiency.

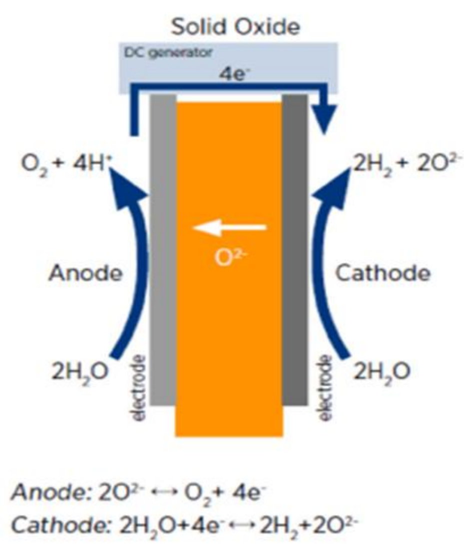

Figure 2: *SOEC reaction mechanism [16].*

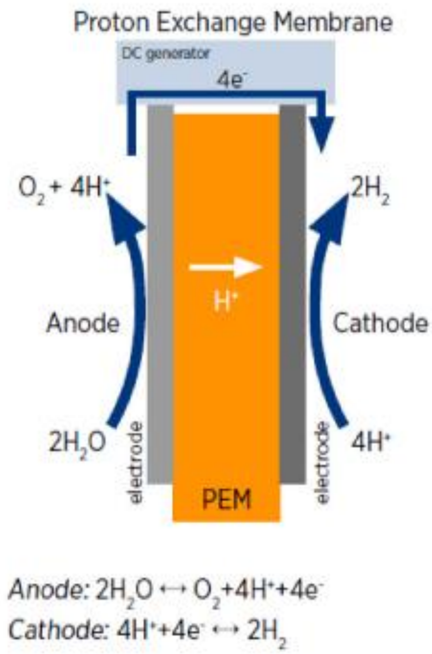

Figure 3: *PEM water electrolyzer schematic diagram and reaction mechanism [16].*

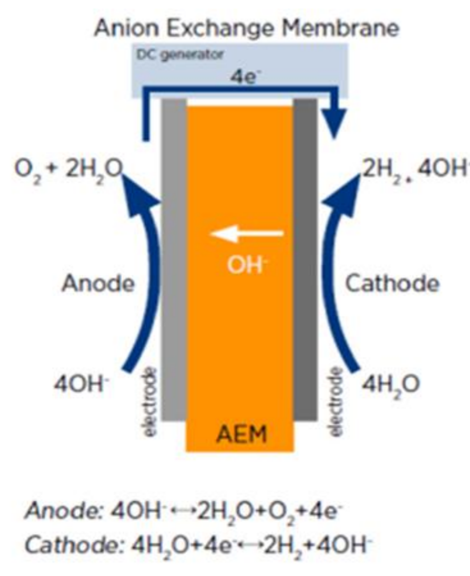

Figure 4: *Alkaline water electrolysis technology [16].*

Scientific research in the field of water electrocatalysis using metal nanoparticles is actively being pursued, and numerous metals have been tested for their catalytic properties. Some of the materials include [19]:

- Platinum nanoparticles (Pt): Although platinum is an expensive metal, platinum nanoparticles exhibit high electrocatalytic activity in water electrolysis.

– Iridium nanoparticles (Ir): Iridium can be used as a catalyst for efficient water electrolysis, especially in combination with other materials.

– Rhodium nanoparticles (Rh): Rhodium has also been investigated as a catalyst for water electrolysis.

- Nickel nanoparticles (Ni): Some research focuses on the use of nickel nanoparticles and their alloys, which may be more affordable compared to precious metals.

– Iron nanoparticles (Fe): Iron and its alloys are also considered as catalysts, especially in combination with other materials.

Nanoparticles provide a larger surface area for interaction with reactants, which can enhance process efficiency. However, besides the material itself, the architecture and structure of nanoparticles also play an important role in determining their catalytic properties [17].

In an experiment conducted by us under laboratory conditions, the coating applied to the metal surface using iron (Fe) method exhibited high operational characteristics, low cost, and a very short and simple production process duration compared to other coatings.

Each method has its unique advantages and limitations, and their application in Azerbaijan will depend on available resources, technical capabilities, and the country's energy and environmental strategy goals. Developing a balanced and sustainable hydrogen production strategy can help Azerbaijan utilize its potential for producing and using this clean energy source.

Let's assume that wind energy is used for water electrolysis to produce hydrogen. In this case, wind turbines generate electric current, which is then used in the electrolyzer to split water into hydrogen and oxygen. The process of producing hydrogen from water (H_2O) using electrolysis looks as follows:

$$2H_2O(l) + \text{electric current} \rightarrow 2H_2(g) + O_2(g)$$

At the anode, water oxidation occurs, forming oxygen (O_2), and at the cathode, hydrogen (H_2) is formed [18].

The advantages of such an approach include:

1. Use of renewable energy: Wind energy is a renewable energy source, allowing hydrogen production with minimal environmental impact and without greenhouse gas emissions.

2. Reduction of dependence on fossil fuels: Producing hydrogen using wind energy helps reduce dependence on fossil fuels and ensures a more sustainable energy system.

However, it should be noted that implementing such a system requires appropriate infrastructure for wind energy generation, hydrogen storage, and utilization. The efficiency and economic viability of this approach should also be considered based on specific conditions and regional characteristics.

The technology for obtaining hydrogen from water is called water electrolysis. This process involves splitting water into hydrogen and oxygen under the action of an electric current. This requires the use of an electrolyzer - a device containing electrodes and electrolyte through which the electric current passes (Fig. 5).

Brief outline of water electrolysis technology:

Step 1: Preparation of the electrolyzer.

The electrolyzer consists of an anode and a cathode separated by an electrolyte, which allows for the passage of ion current between the electrodes. The electrolyzer is filled with water or a solution of alkali or acid to create a conducting medium. These solutions provide the presence of ions in the water, allowing the passage of electric current through the water, causing the decomposition of water into hydrogen and oxygen [19].

The electricity consumption for producing one cubic meter (m^3) of hydrogen can vary significantly depending on the technology used, type of electrolyzer, system efficiency, energy source, and environmental conditions. Additionally, it is important to consider the temperature and pressure at which hydrogen production occurs, as these factors can also affect process efficiency (Fig.6).

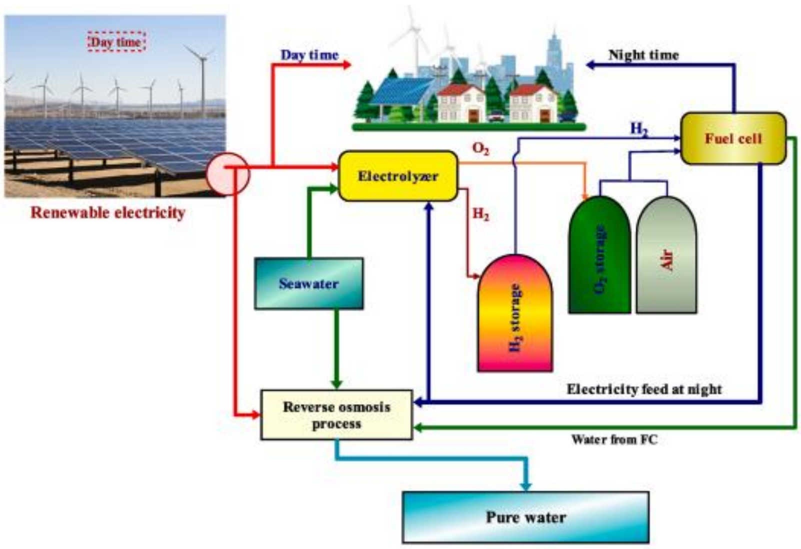

Figure 5: *Proposed integrated system for meeting energy and clean water needs using seawater [17].*

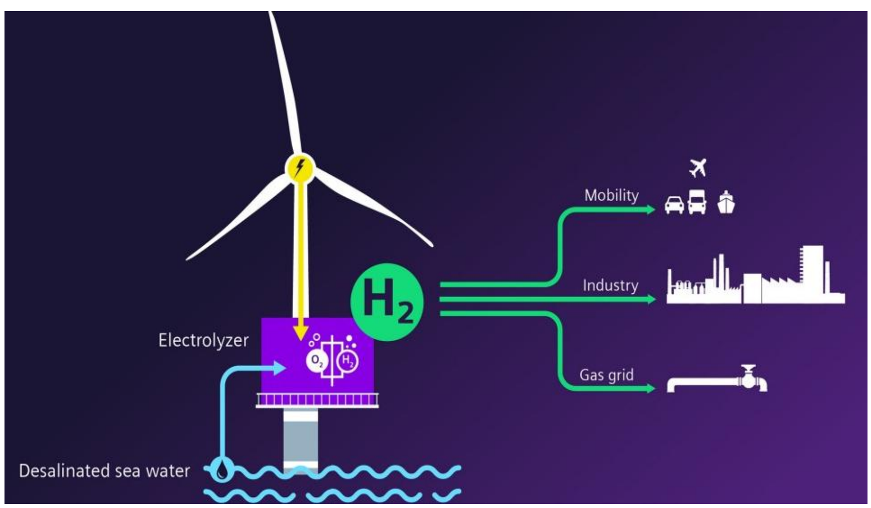

Figure 6: *Schematic structure of the electrolysis-polluted lake - H2Mare [20].*

An approximate estimate of the electricity consumption for producing one cubic meter of hydrogen by water electrolysis is about 4-6 kilowatt-hours (kWh). This value may vary in different systems and conditions, and precise values require more detailed data.

The cost of the electricity source, as well as the efficiency of the production process, will impact the overall energy expenditure of hydrogen production. Producing hydrogen using renewable energy sources such as solar or wind power can reduce environmental impact and make the process more sustainable in terms of climate aspects.

The water consumption for obtaining one cubic meter (m^3) of hydrogen via electrolysis depends on the chemical reactions that occur in the process of water decomposition into hydrogen and oxygen [21].

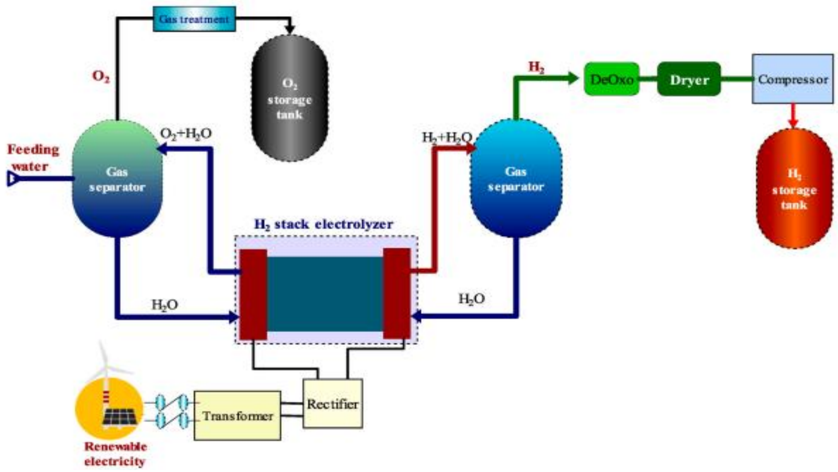

Figure 7: *Basic scheme of H2 and O2 production, including an electrolyzer [17].*

5. Heat Release of Hydrogen

1. Hydrogen has high heat release upon combustion, making it an efficient energy source. The primary reaction during hydrogen combustion is the combination of hydrogen with oxygen, forming water and releasing a significant amount of heat [22]:

Heat release of hydrocarbons (e.g., gasoline or diesel fuel):

$$2H_2+O_2\rightarrow 2H_2O+\text{heat}$$

2. Hydrocarbons also have high heat release upon combustion. The primary components of hydrocarbon fuels are carbon and hydrogen, and the combustion reaction is similar to that of hydrogen:

$$CnHm + (n + m/4)O_2 \text{->} nCO_2 + m/2H_2O + \text{heat}$$

3. Heat Release of Biomass: Biomass, such as wood or agricultural residues, is also an energy source. Its heat release is associated with the combustion process of organic materials, such as cellulose and lipids:

$$C6H10O5+6O2\rightarrow 6CO2+5H2O+\text{heat}$$

6. Environmental Consequences of Renewable Energy Production from Polluted Lakes

While producing green energy from polluted lakes on the Apsheron Peninsula may have significant environmental benefits, such as improving water quality and restoring ecosystems, it may also have certain environmental consequences that need to be considered and minimized. Below are some potential environmental consequences of renewable energy production from polluted lakes:

- Ecosystem Alteration: Infrastructure construction for green energy production may lead to changes in lake ecosystems and surrounding areas. This can affect local plant and animal species, as well as the region's biodiversity [23].

- Loss of Natural Areas: Building hydroelectric power stations or other infrastructure for green energy production may require the allocation of natural land areas, potentially resulting in the loss of ecologically important territories or biological corridors for animal migration.
- Hydrological Regime Alteration: Operating hydroelectric systems may alter the hydrological regime of lakes and water bodies, which can impact their ecological condition as well as plants and animals dependent on this regime.
- Potential Increase in Water Consumption: Large amounts of water may be required to cool hydroelectric power station equipment, leading to decreased water levels in lakes and water bodies. This could negatively affect local flora and fauna, as well as water availability for the local population.
- Risk of Harmful Substance Emissions: While producing green energy from water is considered environmentally cleaner compared to traditional energy sources, there is a risk of emitting harmful substances into the environment due to accidents or improper equipment operation [24].

To minimize these environmental consequences, a comprehensive analysis of potential impacts is necessary. Furthermore, appropriate environmental protection measures should be developed and implemented, along with effective project management for green energy production projects considering environmental aspects.

7. Economic Justifications

The economic efficiency and payback period of capital investments in green energy production technology from polluted lakes on the Apsheron Peninsula may depend on various factors such as construction and maintenance costs, electricity prices, government support, and others.

To do this, it is necessary to take into account not only capital investments but also operating expenses, taxes, inflation, discount rate, and other factors. However, for simplification of calculations, let's focus only on capital investments and assume that all project revenues go towards repaying capital investments [25].

First, let's determine the annual income from hydrogen and oxygen production using windmill electricity:

Annual income = (electricity = 4800 kWh * $0.0388 * 8760 h) + (hydrogen 84.096 x 0.49 x 8760 h) = $1.632 + $360.974 = $1.993 thousand.

Payback period = Capital investments / Annual income

Payback period = $12,000 / $1,993 = 6 years

Conducting comprehensive economic analysis and developing a business plan for the project will help accurately determine its economic efficiency and payback period. Considering the potential environmental benefits and incentives for using renewable energy, as well as the growing demand for green energy worldwide, projects of this kind can have significant potential for successful implementation and economic success.

III. Results

Despite the identified pollution of water bodies in the Apsheron Peninsula with heavy metals, oil products, and the presence of coliform bacteria, hydrogen in this context can be identified as a potential resource that can be used for clean and sustainable energy.

The heat release of hydrogen is an important parameter when considering it as an energy carrier. Hydrogen has high potential as a clean energy source, and its use becomes increasingly relevant with the growing interest in alternative energy sources.

The developed technology for hydrogen production from polluted lakes on the Apsheron Peninsula represents an innovative and sustainable solution capable of contributing to the efficient generation of electricity to operate oil wells. The main stages of the process include electrolysis of water using renewable energy sources, purification of polluted lake water, and obtaining high-quality hydrogen. After that, hydrogen can be integrated into the energy system, providing stable and clean energy supply to oil wells.

This technology has significant advantages, such as sustainable use of local resources, including polluted lakes, for energy production, reduction of greenhouse gas emissions, and improvement of the environmental situation in the region. At the same time, it contributes to strengthening energy independence and increasing the efficiency of the oil industry.

It is important to note that successful implementation of this technology requires joint efforts from scientific and engineering teams, government agencies, investors, and the business community. However, the potential benefits in the form of sustainable energy, reduced environmental pollution, and improved economic efficiency make this approach highly attractive and promising for further research and practical implementation.

FREE OSCILLATIONS OF EARTHQUAKE SOURCE

Felix Aptikaev
•
Schmidt Institute of Physics of the Earth, RAS, RUSSIA
felix@ifz.ru

Abstract

The purpose of the work is to establish the peculiarities of ground vibrations in the near-field zone. The fact is that the existing ideas about generation and propagation of seismic waves in this zone poorly agree with empirical data. The ground vibrations in this zone during explosions and earthquakes are compared. A method of plotting the level of the day surface as a function of time after the moment of explosion is proposed. As a result of ground motion analysis, it is concluded that stresses in rocks during explosion are released in the form of damped standing waves. The amplitude of such oscillations far exceeds the level of generated volumetric seismic waves. And since the mass of oscillating rocks is much greater than the mass of the near-surface layer of ground, the latter have practically no effect on the spectrum and duration of oscillations. Similar processes in earthquakes differ only in the fact that the stresses in rocks exist before the beginning of movement along the fault. The verification showed that in contrast to the ideas about wave generation and propagation used in normative documents of earthquake-resistant construction, the parameters of vibrations in the near-fault zone do not depend on ground conditions. This fact is noted by many researchers. Consequently, many provisions of building codes should be revised. For example, the ground models used in NERA, STRATA, etc. programs are based on the assumption of passing waves and therefore the use of these programs is inappropriate.

Keywords: magnitude, source, fault, near-field and far-field zones of the earthquake, parameters of seismic ground motion, increment of seismic intensity

I. Introduction

Sometimes, the source of an earthquake is often defined as a rupture in rocks or a system of ruptures that occurred in the Earth and led to an earthquake. This definition corresponds to the fault plane as a model for the source of seismic waves. But energy cannot exist outside a certain volume.

Closer to the truth is the definition of an earthquake source as an area in which part of the deformation energy of rocks is converted into the energy of seismic waves. Even such a definition is too simplified. The processes of wave generation and propagation in the source zone remain unknown. There are no estimates of the shape and size of the source zone. The assumption of the source as a realized accumulated strain energy in some area corresponds to small sizes compared to the estimates of such areas from seismotectonic data.

The same applies to the size of aftershock regions. As early as 1935, Charles Richter spoke about the existence of primary and secondary aftershock zones [1]. It is quite probable that secondary aftershocks occur outside the origin and their appearance is the result of stress relief in the origin zone of the main shock. But how to separate primary and secondary aftershocks is still unknown.

Finally, the empirical data do not correspond to the characteristics of known types of seismic waves. According to empirical data, near the fault the amplitudes on soft ground are no higher than on hard ground [2 - 9].

II. Methods

Observations of explosions provide great assistance in studying the processes of generation and propagation of seismic waves. This method has the following advantages. The relative energy of the source is known. The exact time and location of the source are known. This makes it possible to organize a dense network of geophones near the epicenter.

Employees of the Schmidt Institute of Physics of the Earth (IPE) have studied the records of strong ground motions due to explosions, and came to the conclusion that it is impossible to explain the wave field using known types of seismic waves.

The author tried to consider on the field observations materials, obtained by IPE employees, not the level of oscillations at the geophone locations, as usual, but the levels of the day surface at different moments of time [10].

It was shown that the stresses arising in the environment cause, in addition to the known waves, free oscillations of a certain volume of rocks, surrounding the epicenter. The levels of the day surface at different moments of time for one of the explosions, taken from the above-mentioned work, are shown in Figure 1.

There is shown the vibrations of the day surface (vertical component) during an ejection explosion using dispersed charges with a total weight of one thousand tons. The distance between geophones is 100 m.

The first construction was made 0.35 sec after the explosion. The first arrival of shock waves corresponds to a distance of about 650 m. An oscillatory motion is observed with a maximum at a distance of 400 m and a minimum at a distance of 300 m.

After 0.45 s, we can talk about a formed P-wave with the first entry at approximately 820 m. The speed of this wave is about 2 km/sec. The amplitude of the minimum, which was observed after 0.35 sec at a distance of 300 m, took on a negative value (under the previously level).

After approximately 0.75 sec, the ground surface becomes close to the original one. Seismic body waves disappear beyond the considered range of distances. Fluctuations at distances of 600 m and 700 m have practically ceased. But the free vibrations of rocks do not stop.

After 0.9 sec, the amplitude at the same distance of 300 m takes on a maximal positive value.

After 1.5 sec, the amplitude again takes on a maximal negative value.

It can be concluded that the stress resulting from the explosion in the surrounding rocks is "reset" in the form of standing damped oscillations of the medium. Moreover, the amplitude of these oscillations is much higher than the generated traveling seismic waves.

Similar phenomena should occur during earthquakes. The only difference is that during earthquakes, stress in the rocks exists even before movement along the fault begins. The characteristics of seismic vibrations that confirm this hypothesis are considered.

Using empirical material, it is shown that other parameters of oscillations in the focal zone of earthquakes - the predominant period and the duration of oscillations - do not depend on ground conditions. However, seismic intensity on soft ground increases due to a decrease in the bearing capacity of the ground. Previously, only soil liquefaction was usually considered such a factor. However, there is a method for vibrating piles to significant depths (up to 70 m) without the liquefaction process. At acceleration amplitudes on the vertical component PGA > 0.1 g, the shear strength of soft ground in the horizontal plane can decrease several times. This phenomenon is also observed for hard ground, but to a weaker extent [11 - 13].

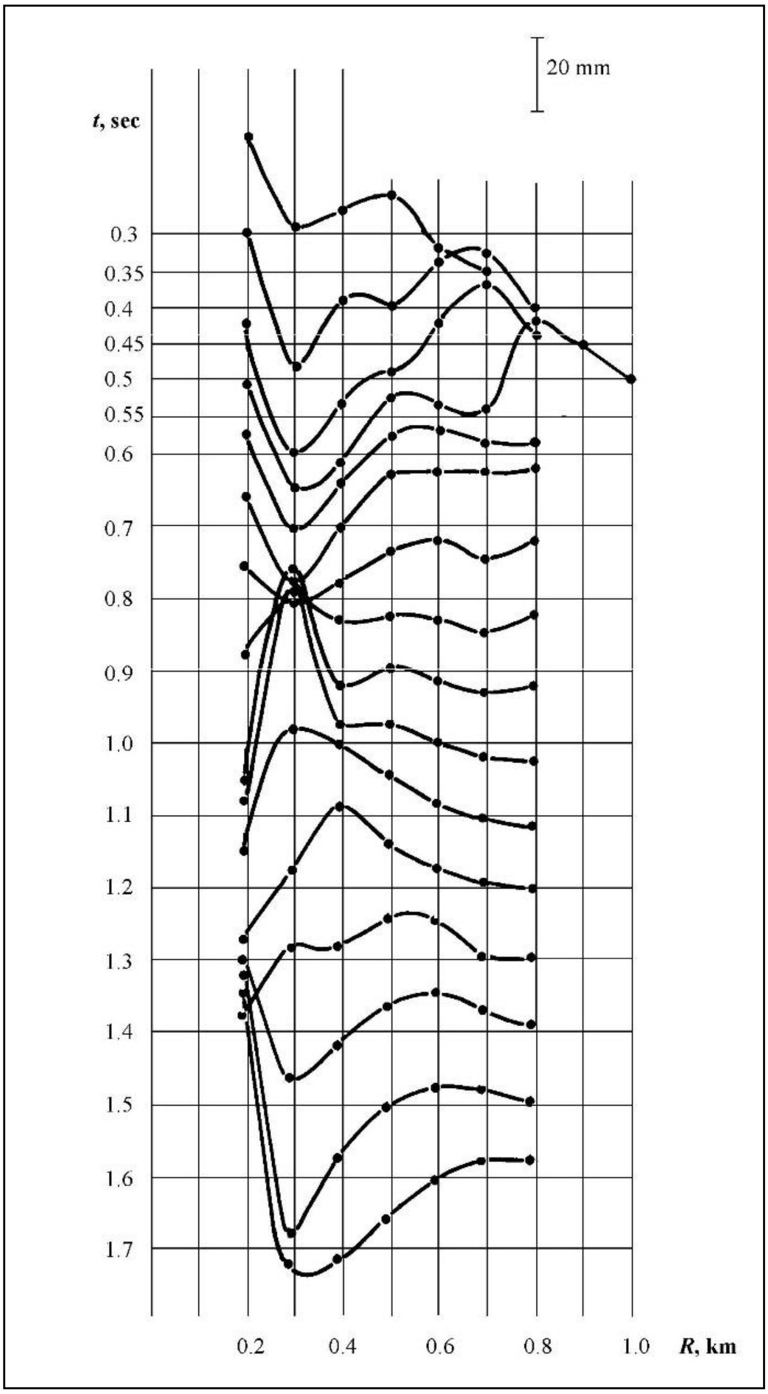

Figure 1: *The levels of day surface for different times for explosion of 1 kt (from [10])*

III. Results

It turned out that the influence of movement along the fault is limited in space. In the engineering range (intensities of 7 – 9 points), three zones were identified in which not only the attenuation laws, but also the dependences of the parameters of seismic ground motion on focal mechanism and ground conditions are different [14].

In the near-field zone the attenuation coefficient is noticeably lower than unity, and in the far-field zone it is much greater than unity. Consequently, seismic wave energy is released in the near-field zone, and this energy is absorbed in the far-field zone. The boundary of the source corresponds to the distance

$$\log R_g = -0.77 + M / 3, \quad (1)$$

where R_g is the shortest distance to the rupture surface,
M – magnitude based on surface waves.

Accordingly, the seismic source has the shape of a parallelepiped with smoothed edges.

Often the natural vibrations of the source are mistaken for a S - wave. In this case, estimates of the hypocentral distance from the difference in arrivals of S- and P - waves will be incorrect.

For some reason, the resonant properties of ground according to the building code is usually determined not on the basis of statistical processing of records obtained on various ground types, but on the basis of models of ground strata such as NERA, STRATA and others. Errors in using such programs are associated with the assumption of passing waves.

Empirical data indicate that the parameters of ground motion in the near-field zone are virtually independent of ground conditions [9, 15]. Thus, the seismic intensity increment in the near-field zone is related to the bearing capacity of the ground.

From the theoretical point of view, the parameters of natural oscillations do not depend on the ground conditions because of the mass of the source rocks is much greater than one of the 30-meter layer on one of the source surfaces. Consequently, seismic intensity increments can be related only to the bearing capacity of the ground. There are known cases when practically undamaged buildings plunged into the ground and tilted strongly. This was attributed to liquefaction of the ground. However, significant ground subsidence can occur without liquefaction. There is a method of vibropiling piles to considerable depths (up to 70 m) and without the liquefaction process.

The influence of ground conditions on the parameters of seismic ground motion is valid only in the far-field zone. Moreover, only half of the increase in seismic intensity is associated with a change in amplitude, and the second half is associated with a change in the duration of oscillations. The last factor, according to empirical data, has the same effect on the damageability of construction objects as the acceleration amplitude. Unfortunately, this factor is not yet taken into account in Russian building codes. In other countries the influence of the duration of oscillations on seismic intensity is accounted for by Arias' formula [16].

Since instrumental estimates of seismic intensity based on accelerations, velocities and displacements generally do not coincide, one can think that the spectral composition of vibrations also affects seismic intensity.

IV. Discussion

Damage to construction objects in the source zone (fault and near-field zones) is related to the free vibrations of the source and is determined only by the magnitude of the earthquake. Parameters of ground motions are independent on ground conditions. Accordingly, it is necessary to develop a system of ground parameters to which the seismic intensity increment refers.

In the far-field zone not amplitude of acceleration only, but all the parameters of ground motion (predominant period and duration of oscillations) depend on ground conditions.

Since instrumental estimates of seismic intensity based on accelerations, velocities and displacements generally do not coincide, one can think that the spectral composition of vibrations also affects seismic intensity [17].

NATURAL AND MAN-MADE CLIMATE CHANGES IN THE HOLOCENE

Rustam Gakaev[1], Arun Daukaev[2]

•

[1]Kadyrov Chechen State University, RUSSIA
[2]Kh . Ibragimov Complex Institute of the RAS, RUSSIA
rustam.geofak@yandex.ru

Abstract

The article provides a comprehensive analysis of both natural and anthropogenic climate variations over the Holocene epoch, spanning the last 11,700 years. It begins by exploring the natural drivers of climate change, including Milankovitch cycles, which influence Earth's orbital parameters and contribute to long-term climatic shifts, volcanic eruptions that inject aerosols into the atmosphere, and changes in solar irradiance. These factors played a critical role in shaping early Holocene climate patterns, leading to periods of warming and cooling, such as the Medieval Warm Period and the Little Ice Age. As the article progresses, it shifts focus to the growing impact of human activities, particularly from the advent of agriculture and urbanization to the present-day industrial era. The study discusses how early human practices like deforestation, large-scale farming, and the domestication of animals gradually began to influence local and regional climates. However, it is in the post-industrial era that human influence on the climate has dramatically accelerated, primarily due to the combustion of fossil fuels, mass deforestation, and the significant rise in greenhouse gas emissions. This shift marks a transition from predominantly natural climate drivers to an era increasingly dominated by human-induced climate forcing.

Keywords: Holocene, natural climate variability, anthropogenic climate change, volcanic activity, solar insolation, greenhouse gas emissions, deforestation, industrial

I. Introduction

Climate changes have taken place throughout nearly all geological eras and are documented through paleontological discoveries, shifts in archaeological cultures, and other forms of evidence. However, the use of archaeological data for stratigraphic analysis and other studies is limited to the Quaternary period, as it was during this time that a key event occurred: the emergence of humans. Consequently, this period is also known as the Anthropogenic. Fossil remains and artifacts from human material culture serve as the primary paleontological markers for the subdivisions of the Quaternary period. The archaeological method, alongside paleontological research, is applied in various disciplines, including climatology. The Anthropogenic (Quaternary) period is divided into the Pleistocene and Holocene epochs. The Pleistocene is further subdivided into a series of glacial and interglacial stages, including the Günz, Mindel, Riss, and Wurm glaciations, and the Günz-Mindel, Mindel-Riss, and Riss-Wurm interglacial stages.

The Holocene epoch, the focus of this article, represents the second and current epoch of the Quaternary period. In July 2018, the International Union of Geological Sciences (IUGS) officially divided the Holocene into three distinct ages, each marked by climatic shifts: the Greenlandian (11,700 to 8,200 years ago), the Northgrippian (8,200 to 4,200 years ago), and the Meghalayan (from 4,200 years ago to the present), as classified by the International Commission on Stratigraphy. The Greenlandian is characterized by warming after the last ice age. The

Northgrippian is notable for a significant cooling event triggered by the disruption of ocean circulation due to glacial melt. The current age, the Meghalayan, began with a severe drought lasting around 200 years [Fagan, 2021].

The Holocene epoch began around 11,700 years ago, following the Pleistocene, and is the shortest geological epoch, except for the debated Anthropocene, which some scholars argue started in the 1950s. This epoch is marked by significant global warming, the extinction of Pleistocene megafauna, and the broader Holocene extinction, as well as the spread and social evolution of Homo sapiens.

Due to its distinctive climatic characteristics, the Holocene is generally considered an interglacial epoch, showing many similarities to previous interglacial periods. The primary trend in Holocene climate change was the shift from the cold conditions of the late Pleistocene to a warmer climate, with the peak of warming occurring approximately 6,000 years ago. Although the overall climate during the Holocene was relatively stable, researchers have noted considerable variability.

Roughly 14,000 years ago, the Earth's temperature began to rise, initiating the melting of glaciers and the breakup of ice sheets. This warming was global in scope and led to the degradation of the Wurm ice sheets in Europe and the Wisconsin ice sheets in North America. During this process, there were notable fluctuations in temperature, periodic glacier advances, changes in sea levels, the altitude of snow lines in mountain regions, and the extent of valley glaciers and vegetation zones. The Scandinavian ice sheet disappeared about 9,000 years ago, while the North American ice sheet followed around 7,000 years ago.

II. Methods

Based on paleobotanical data, the Holocene is divided into the following climatic periods: Arctic and Subarctic (end of glaciations and beginning of the postglacial period); Boreal (9,000–7,000 years ago) — cool and dry; Atlantic — warm and humid; Subboreal — warm and dry (xerothermic); and Subatlantic — cool and humid [Holocene climate..].

In the Arctic and Subarctic period (11,000–10,000 years ago), warming not only led to the retreat of ice sheets in North America and Europe, but also to the significant reduction of tundra in Europe. Birch-pine and taiga forests began to expand once again.

During the Boreal period, taiga forests continued to spread northward, replacing the tundra, while broad-leaved forests began to dominate southern and central Europe. The melting of glaciers contributed to a rise in sea levels. This period coincided with the Mesolithic (Middle Stone Age), characterized by the increasing settlement of permanent locations, marking a shift toward a more sedentary lifestyle. People still relied on hunting and gathering, although agriculture began to emerge in some regions, and the clan community was the basic social unit.

Around 6,000 years ago, the Holocene climatic optimum began, which is associated with the Atlantic period. According to the Blytt-Cernander classification, the Atlantic was the warmest and wettest phase of the Holocene in Northern Europe. During this time, temperatures were generally higher than today, and half of Iceland was covered in birch forests, compared to just 1% today. The vegetation in Europe was more diverse and included more heat-loving species. The temperate forest zone extended about 5° further north than its current location, and the average annual temperature in Europe was 1-2°C higher than today. In tropical regions, the climatic optimum brought increased humidity and a slight rise in temperature. The Sahara was a savanna, and Lake Chad’s water level was 40 meters higher than its current level (11 m). Evidence from different regions in both hemispheres indicates that the Holocene optimum was marked by a warm, humid climate on a global scale.

The Subboreal period (5,000–2,500 years ago) was characterized by cooling, which caused a southward shift of landscape zones toward the equator. This period saw the advance of mountain

RT&A, Special Issue № 6 (81), Part-2,
Volume 19, December 2024

glaciers in Alaska, Spitsbergen, Iceland, and the Alps, as well as increased ice cover in higher latitudes and greater aridity in already dry regions.

The Subatlantic period, which began about 2,500 years ago (500 BCE) and continues to the present day, brought cooler and wetter conditions. During this time, the climate deteriorated, becoming cooler with increased precipitation, particularly in parts of Europe where precipitation rose by 1.5 times. Peat bogs began to form, and the tundra expanded into forest areas, while forests encroached upon the steppe. Gradually, the climate shifted toward modern conditions, characterized by higher oceanicity. In the early centuries CE, temperature and humidity were similar to today's levels, but by the 4th–5th centuries CE, the climate became dry and warm until the 8th century, during which time peatlands contracted, and lake levels dropped.

III. Results

Khotinsky N.A. and Savina S.S. conducted a detailed analysis of the ancient climate of the former USSR during the Holocene period [1985]. Earlier, N.A. Khotinsky, using paleobotanical research and radiocarbon dating data, identified three major warm phases of the Holocene within the USSR: the Boreal phase (8,300–8,900 years ago or the 7th millennium BCE), the Late Atlantic phase (the climatic optimum, 4,700–6,000 years ago or the 3rd millennium BCE), and the Mid-Subboreal phase (3,200–4,200 years ago or the 2nd millennium BCE). He also determined that the Boreal warming was most prominent in the Northeast and Far East of the USSR, the Late Atlantic phase was widespread across most of Eurasia, and the Mid-Subboreal phase was particularly significant on the northern Russian Plain.

Several researchers, based on paleoclimatic studies, observed that the warm, humid climate of the 4th millennium BCE transitioned into a hot and dry (arid) climate during the 3rd millennium BCE [Idrisov, 2010]. By the middle of the 3rd millennium BCE, the sedentary Kura-Araxes agricultural society was replaced by a population with a radically different economic system [Kornienko, 2013]. Numerous scholars have similarly linked shifts in archaeological cultures to corresponding climate changes [Munchaev et al., 2012].

In the first centuries CE, temperature and humidity levels were comparable to modern conditions. However, between the 4th and 8th centuries CE, the climate in Europe became drier and warmer, leading to the shrinking of peatlands and falling lake levels. During the Medieval Warm Period (7th to 14th centuries CE), the climate in the Northern Hemisphere became notably milder and warmer, causing a sharp reduction in the ice cover of the northern seas. This period, also known as the Medieval Climatic Optimum, featured mild winters, expanded agricultural land, and a notable increase in both food production and population. Some American researchers suggest that the classical Mayan civilization collapsed during this time due to prolonged droughts [Medieval Climatic Optimum]. In the Caucasus, there was a significant retreat of glaciers in the Greater Caucasus, increased river flows from glacial melt, a drop in the Caspian Sea level, and the formation of deflation basins, all indicative of a warmer climate [Phys. geog. CR, 2006].

By the 14th century, a new phase of cooling had begun. Ice cover in the northern seas increased, and intra-seasonal climate variability also grew, marking the onset of the Little Ice Age. Some sources date the beginning of this period to the 14th century, while others place it in the 17th century, with its effects lasting until the mid-19th century. Key characteristics of the Little Ice Age include the expansion of mountain glaciers and a decline in arable and pasture land. This period is discussed in detail in B. Fagan's book published in 2021 [Fagan, 2021]. However, some researchers, such as A.S. Monin and colleagues, argue that the term "Little Ice Age" is inappropriate, as there was no continuous cooling over the entire period [Monin et al., 1979].

In the Caucasus, the Little Ice Age manifested through a rise in the Caspian Sea level, a weakening of continental climate patterns, increased precipitation, and other features [Phys. geog.

CR, 2006].

IV. Discussion

In the 16th century, the Alpine glaciers began to advance noticeably, but by around 1700, some retreat was observed. However, at the same time, glacier growth was recorded in Iceland and Norway, with a maximum in Sweden occurring around 1710. Significant glacier movements occurred again in the 1720s in the Alps, Scandinavia, the USA, and Alaska. In Alaska, glaciers had already started advancing into the valleys from the 14th century. After some stabilization in the late 16th century, Alaskan glaciers resumed their advance. In the 1740s-1750s, particularly strong glacier advances occurred in Northern Europe, Iceland, and Alaska. Glacier expansion in the Alps continued through the 1760s-1790s, reaching a maximum in 1820. A global peak in mountain glaciation in regions such as the Alps, Iceland, Norway, North America, and the Patagonian Andes was noted in 1850. The last significant global glacier movement occurred between 1850-1860, marking the end of the Little Ice Age.

The timing of climatic changes during the Little Climatic Optimum and the Little Ice Age varied between different regions of the Earth. The exact causes remain unclear, but some hypotheses suggest increased volcanic activity and a decrease in atmospheric CO_2 concentrations as potential factors behind the Little Ice Age.

After the Little Ice Age, a warming period began in the late 19th century, with particularly pronounced warming during the 1920s and 1930s. Climate fluctuations in the late 19th and 20th centuries were measured directly through meteorological observations. In many parts of the world, such as the Caucasus, Pamir, Tien Shan, Altai, and the Himalayas, glaciers retreated during this period, leading to a reduction in their overall area. For instance, the glacier area in the Caucasus shrank by 8.5% between 1890 and 1946 [Modern climate, Internet resource]. Other data, including long-term monitoring from the High-Mountain Geophysical Institute in Nalchik, indicate that glacier coverage in the Greater Caucasus decreased by 40% over the last century.

By the 1940s, this warming trend reversed, leading to a cooling period that peaked in the mid-1960s. Glacier expansion occurred in the early 1960s as a result. However, since the 1970s, a new phase of warming began, which persists today [Monin, 1979]. Since the 1990s, there has been an increase in precipitation, a rise in the Caspian Sea and groundwater levels, and a continued reduction in glacier areas.

There is substantial evidence that the warming following the Little Ice Age extended into the late 19th and early 20th centuries. Instrumental observations show that the average global temperature increased by 0.5°C during this period. Rising global temperatures impact the ocean, causing thermal expansion and, consequently, sea level rise. Changes in precipitation distribution over land have also been observed. Since the early 20th century, sea level measurements show a consistent rise, with an average increase of 4-5 cm per century. Therefore, the past 100 years have been characterized by a period of climate warming.

Since the 1970s, a new phase of global warming has prompted widespread attention to the future of Earth's climate. Various explanations for the causes and consequences of climate change have emerged. The first theory attributes climate change to human activities, particularly the industrial use of hydrocarbon fuels, which has intensified the greenhouse effect. The second theory suggests that global warming is driven by cosmogenic factors, unrelated to human activity. A third theory posits that climate change is a result of the synergy between both anthropogenic (greenhouse effect) and natural processes [Global climate change].

Academician V.M. Kotlyakov acknowledges the greenhouse effect's existence but highlights the difficulty in determining its exact contribution to global climate change. Carbon dioxide is the primary contributor to the greenhouse effect, and efforts to reduce its emissions include transitioning from traditional fossil fuels to renewable energy sources. The Kyoto Protocol (1997) and the Paris Agreement (2015) have been pivotal in setting international standards for reducing CO_2 emissions. In response, renewable energy has gained increasing attention, with the share of renewables in the global energy mix growing to 14% over the past 50 years [Degtyarev, 2022]. Looking forward, population growth and economic expansion will shape global energy demand, with projections indicating a decrease in the use of oil and coal and an increase in gas and renewable energy. According to the World Energy Council, renewable energy sources could surpass 40% of the global energy balance [Salygin, 2021].

Thus, climate change in the Holocene, as in earlier geological epochs, is largely a natural historical process. Following the glacial and interglacial periods of the Pleistocene, the Holocene has witnessed alternating periods of warming and cooling, punctuated by shorter episodic climate shifts. The current warming phase, which began in the 1970s, continues today. However, the industrial revolutions and the increasing consumption of fossil fuels have introduced a significant anthropogenic factor into this natural process.

Abstract

While studying the structural and group composition of aromatic hydrocarbons in liquid fractions of the products of catalytic oxycracking of vacuum gas oil, as well as their molecular weight distribution, it was revealed that monocyclic aromatic hydrocarbons predominate in their composition. Their concentration is lower than in the traditional catalytic cracking sample and decreases in 1% OCC > CC > 2% OCC. Among the identified polyaromatic hydrocarbons, naphthalene and its homologs dominate at 1% oxycracking, and phenanthrene and its homologs dominate at 2% oxycracking; at a 1% degree of oxidation, the amount of naphthalene exceeds the indicators of traditional catalytic cracking by almost 2 times, while at a 2% degree of oxidation, this figure decreases by 4 times, which is the smallest among the studied samples. The cresol content also increased significantly. The concentration of fluorene, phenanthrene, and anthracene decreases, but only slightly. In oxycracking products at a 2% degree of oxidation, the content of all PAH groups is the lowest among the samples under consideration. The trend towards a drop in benzo-containing PAHs, noted for traditional catalytic cracking products, is also true for this sample.

Keywords: catalytic oxycracking, vacuum gas oil, aromatic hydrocarbons, naphthalene, cresol, phenanthrene

I. Introduction

The concentration of aromatic hydrocarbons (AHC) is successfully used instead of individual lower homologs of benzene (toluene, xylenes) as solvents for varnishes, enamels, and paints [1-4]. Aromatic solvents are produced: light with the content of C9-C10 arenes - 98% (wt.), medium with 97.3% (wt.) arenes of the naphtha fraction and heavy, containing 87.6% (wt.) of the arenes of the kerosene fraction. Various areas of use of arenes and aromatic solvents correspond to the boiling limits of gasoline-naphtha fractions. The authors noted that one of the most large-scale areas of use of aromatic hydrocarbons (except for the organic synthesis industry) and their mixtures are solvents, primarily for paints and varnishes. The global solvent market consumes about 15 million tons/year for these purposes, of which 36%, i.e. 5.4 million tons/year, are hydrocarbons [1]. According to Hildebrand solubility parameters, aromatic solvents occupy an intermediate position between paraffin-naphthenic and polar solvents [1]. Therefore, aromatic solvents exhibit high dissolving ability towards both non-polar and polar compounds and polymers.

Another large-scale area for the use of aromatic solvents is the oil production industry - mainly in drilling and cementing wells, stimulating oil flow. Aromatic hydrocarbon solvents are used to displace oil, influence the bottom hole formation zone, and inhibit and remove asphaltene-resin-paraffin deposits.

Aromatic solvents increase the effectiveness of de-emulsifiers during dehydration and desalting of oils. Increasing the concentration of arenes in the absorbent of hydrocarbons from natural gas, for example, replacing the hydrocarbon fraction with a boiling point of about 238 °C and an average molar mass of 180 with mesitylene, led to an increase in the degree of propane extraction from 37.1 to 60.2% [1]. The introduction of arenes (0.01-0.04 mol/l) helps to accelerate radical copolymerization processes, for example, methyl methacrylate with vinyl butyl ether, and increases the proportion of vinyl butyl ether units in the copolymer.

One of the most important areas of use of arenes of middle distillate petroleum fractions is the production of detergents based on both linear alkylbenzenes - n-alkyl-benzenesulfonates, characterized by high biodegradability - and alkylbenzenes with branched alkyl chains. Extracts of aromatic hydrocarbons are used as a softener for rubber compounds, to produce carbon black, etc.

Of interest is the method of intensifying the process of distillation of petroleum residues in the presence of aromatic concentrates [5-8]. Thus, adding 3% (wt.) of the extract of the oil fraction 350-420°C to the vacuum residue of West Siberian oil leads to an increase in the distillate yield by 11.5% (wt.). Various explanations for this effect have been proposed: an increase in the degree of dispersion of the oil system, a change in the degree of solvation of dispersed particles; and increasing the thermal stability of the system, which allows increasing the final temperature of the rectification process. Arene derivatives - alkyl arylsulfonates, Petrov's contact, alkylbenzene synthetic oils, sulfonate additives, and antioxidants - are also widely used.

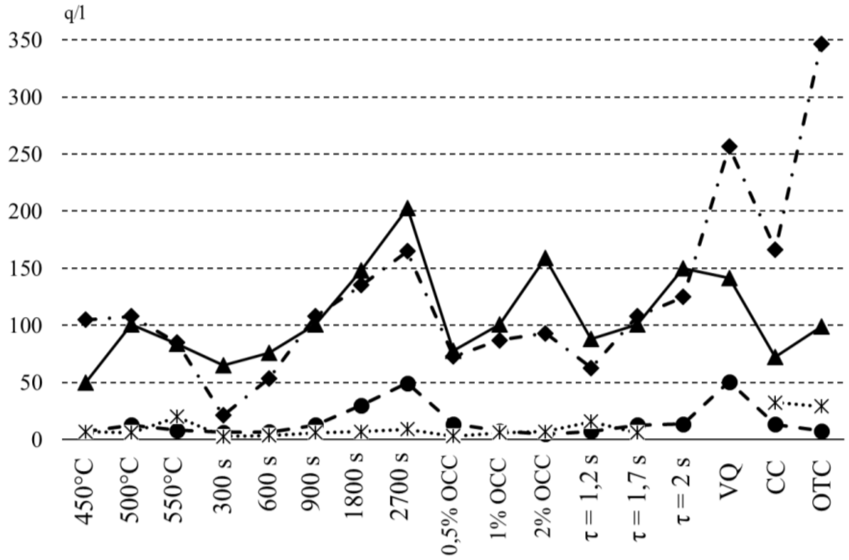
During our previous studies [9-11] of the process of catalytic oxycracking of vacuum gas oil (OCC VG), it was found that increased temperature conditions and high duration and contact time contribute to the formation of a product of a heavy fractional composition. In this regard, studies of the distribution and nature of ArHc are of particular interest for understanding the characteristics of the progression of OCC of VG.

II. Methods

Studies of the oxycracking process [9-11] were carried out in a flow-through installation at atmospheric pressure, at temperatures of 450, 500, and 550°C, with a catalyst volume of 5 cm3. To obtain data on the dependence of quantitative and qualitative indicators of the oxycracking process on technological parameters, it was carried out at 500°C with varying contact time (1.2, 1.7 and 2 s), process duration (300, 600, 900, 1800 and 2700 s), and 0.5, 1 and 2.0% degree of oxidation of the raw material - vacuum gas oil (VG). During the research, experiments of three types were carried out: catalytic oxycracking (OCC) itself, to determine the contribution of the catalyst-non-catalytic oxidative thermal cracking (OTC), as well as a series of experiments of traditional catalytic cracking (CC) under conditions identical to OCC and OTC. The VG OCC process was carried out in the presence of an industrial microspherical cracking catalyst OMNIKAT-210P (manufactured by Grace). The catalyst formed during the experiments was a mixture of both target fractions and unconverted raw materials. Quantitative analysis of hydrocarbons was carried out in a complex consisting of an Agilent 6890N gas chromatograph equipped with a skin with a highly efficient mass selective detector Agilent 5975. Correlation analysis was carried out by calibration with standard reference solutions. A mixture of deuterated polycyclic aromatic hydrocarbons was used as an internal standard: naphthalene-d8, phenanthrene-d10, pyrene-d10, cresol-d12 and perylene-d12 (Cambridge Isotope Laboratories, Inc., Andover, USA). The calculation was carried out based on an external calibration curve. A mixture of 16 polycyclic aromatic hydrocarbons (TCL PAH MIX, Supelco, USA) was used as a standard reference solution.

III. Results

Based on the corresponding characteristic masses of ions, mass fragmentograms of mono-, bi-, and poly ArHc were obtained and the content of the corresponding classes of compounds in VG oxycracking catalysates was determined depending on the process conditions (Fig. 1). The quality of the initial oil fraction, as well as the catalyzer obtained at 500°C for 900 s with a contact time of 1.7 s under conditions during traditional QC and the liquid QC product, is also shown in Fig. 1 and Table 1.



Picture 1: *The influence of OCC process conditions on the individual content in fraction 1 (alkyl-ArH (dotted line)) and fraction 2 (mono-ArHc (dashed line), alkyl-ArHc (solid line) and PaHc (dot-dash)).*

Based on the ArHc content in fraction I (standard gasoline), the catalysates selected at temperatures of 450 and 500°C, OCC duration up to 30 minutes, oxidation degree of 0.5 and 1%, contact time 1.7 s can be classified as types of gasoline with an average ArHc content (3-9%); and under conditions of elevated temperatures - 550°C, durations of 30 and 45 minutes, and contact time of 1.2 seconds - to gasoline with a high ArHc content (>9%). Comparative results of the group hydrocarbon composition of fractions I obtained under the conditions of traditional catalytic and oxidative thermal cracking, presented in the figure, indicate that these gasoline components also belong to highly aromatic products.

In the composition of fraction II of oxycracking samples, a relatively high content of aromatic hydrocarbons is observed (from 24.6 to 59.6% relative to 17.8% in CC), represented by mono-, bi-, and polycyclic structures.

We studied in detail the influence of the OCC process parameters on their nature and distribution due to the high content of ARC in this fraction. Due to the influence of a large number of factors on the content of aromatic hydrocarbons in the oxycracking catalyst, it is almost impossible to unambiguously predict any trend in their formation without describing experimental studies. The highest ArHc content is characteristic of samples obtained under conditions of maximum temperature, oxycracking duration, and contact time. In contrast to these parameters, the degree of oxidation does not have such a significant impact on this indicator. The data obtained indicate the contribution of the catalyst to the formation of ARC under OCC conditions, partly as a result of the same reactions as during traditional catalytic cracking (hydrogen transfer, dehydrogenation of naphthenes and dealkylation of alkyl aromatic hydrocarbons, dehydrogenation and cyclization of olefin hydrocarbons, decomposition of naphthenoaromatic hydrocarbons [12-14]), but mainly due to oxidative dehydrogenation and oxidative dehydrocyclization.

Table 1: *Influence of technological parameters of the oxycracking process on the content of ArHc groups*

[1] process conditions: duration 900 s; temperature 500°C; contact time 1.7 s.

[2] process conditions: duration 900 s; oxidation degree 1%; contact time 1.7 s.

[3] process conditions: temperature 500°C; oxidation degree 1%; contact time 1.7 s.

[4] process conditions: duration 900 s; temperature 500°C; oxidation degree 1%.

[5] thermal oxidative cracking, process conditions: duration 900 s; temperature 500°C; oxidation degree 1%.

[6] traditional catalytic cracking, process conditions: duration 900 s; temperature 500°C; contact time 1.7 s.

* Experimental conditions: duration 900 s; temperature 500°C; contact time 1.7 s, oxidation degree 1%.

When comparing the data obtained, it is also clear that each of the technological parameters individually has a specific effect on the nature of the distribution of mono- and poly-ArHc: with an increase in the degree of oxidation, the content of mono increases against the background of a decrease in poly- ArHc; at 2% the TCC of mono-ArK is absolute majority; with increasing temperature, both types of compounds gradually increase; the process duration of 600-900 s is the interval in which the resulting catalyst has a minimum content of ArHc of both types; An increase in contact time mainly promotes the formation of mono-ArK ArHc

The ratio of the total content of poly-ArHc as products of condensation and the addition of mono ArHc to the content of the latter can indirectly indicate the nature of the ongoing reactions: condensation, addition on the one hand, or isomerization reactions, hydrogen transfer, transalkylation of aromatic hydrocarbons and cyclization, on the other. For comparison, OTK products, being the most aromatized, in which this ratio is 3.58, are probably formed as a result of addition reactions of fused rings, while KK products, in which the poly-/mono- ratio is 2.58, are cyclization, alkylation [13, 14] .

The results obtained indicate that OCC conditions generally favor isomerization, hydrogen transfer, transalkylation, and cyclization reactions. Whereas low-temperature conditions and large oxycracking contacts slightly increase the contribution of condensation reactions of aromatic hydrocarbons.

Chromato-mass spectrometric analysis, which showed the presence of valuable petrochemical products, such as: acenaphthalene, phenanthrene, fluoranthene, etc., determined the concentrations of individual PAHc in oxycracking catalysts (Table 2). A detailed analysis of the distribution of individual PAHc indicates that in the raw materials, the following 5 components dominate: fluorene, phenanthrene, anthracene, benzo(a)anthracene, and cresol. In traditional CC products, the amount of fluorene and anthracene increased by 40% and 17%, respectively, cresol decreased by 60%, and phenanthracene remained virtually unchanged. The main difference was a more than 6-fold increase in the concentration of naphthalene and a decrease in all benzo-containing PAHs without exception.

IV. Discussion

Consideration of the results of the distribution of individual PAHc in oxycracking products made it possible to identify several distinctive features in comparison with the indicators of traditional catalytic cracking. The composition of raw materials - VG, as well as liquid products of its oxycracking and traditional catalytic cracking, includes the same homologous series of aromatic hydrocarbons, monocyclic aromatic hydrocarbons predominate; concentration changes of monocyclic aromatic hydrocarbons: 1% OCC > CC > 2% OCC ; Among the identified polyaromatic hydrocarbons, naphthalene and its homologues dominate at 1% oxycracking, and phenanthrene and its homologs dominate at 2% oxycracking; in oxycracking samples the concentration of ArHc is lower than in traditional catalytic cracking.

Abstract

The article is devoted to the application of nature-compatible solutions for minimizing climate risks and adapting to climate change. The article presents the results of a study on surface runoff in Curonian Spit area using models of the InVEST Urban Stormwater Retention software package. The modeling results identified the most vulnerable area in the Curonian Spit (Baltic Coast) in terms of potential flooding in the context of increasing climate change - specifically, the village of Rybachy. To minimize the climatic risks of flooding and to modernize the rainwater drainage and collection, nature-compatible solutions have been proposed for integration into the existing infrastructure.

Keywords: nature-compatible solutions, adaptation to climate change, risks

I. Introduction

Nowadays, significant attention is devoted to mitigating and adapting to the impacts of climate change. The 2024 Global Risks Report by the World Economic Forum identifies three key climate-related challenges as primary risks facing humanity: extreme weather events, critical changes in Earth's systems, and the loss of biodiversity and ecosystem degradation. Solutions aimed at minimizing risks and adapting to climate change are essential to reduce the effects of rising temperatures, intense storms, water pollution and eutrophication.

Anthropo-natural systems (APS), created through natural processes and human intervention, are particularly sensitive to climate change [1]. One such system is the Curonian Spit - a narrow, elongated, crescent-shaped sandspit separating the Curonian Lagoon from the Baltic Sea. The Curonian Spit has been shaped by the sea, wind, and human activity and continues to be influenced by these factors. After catastrophic human interventions that threatened its existence, the spit was restored through extensive protection and stabilization efforts beginning in the 19th century and continuing to this day. The contemporary cultural landscape of the Curonian Spit has been formed under the influence of both both human and natural forces.

The Curonian Spit is constantly affected by waves and storms, experiencing erosion and flooding, which pose threats to the population and infrastructure of the settlements within its territory. Under changing climate conditions, the frequency and intensity of such events are increasing. Additionally, the rising population and tourist numbers on the Curonian Spit, and the consequent increase in anthropogenic pressure, may lead to the loss and degradation of coastal ecosystems and their ability to protect people during storms. Thus, this topic is particularly relevant; it is crucial to understand the roles of various biological and geophysical factors that can enhance or mitigate the threat of coastal erosion and flooding to better plan future development of the territories [2].

To minimize the climate-related flood risks on in the Curonian Spit area, it is necessary to adopt technologies that can take into account climate change. In these conditions, nature-compatible solutions are most effective, using sustainable management principles and natural properties and processes to solve social and environmental problems. International experience shows that nature-compatible solutions are economically viable and sustainable, offering long-term effectiveness compared to technological investments or the construction and maintenance of infrastructure [3]. In the Russian Federation, nature-compatible solutions are rarely implemented, yet local residents of the Curonian Spit have long adapted to environmental changes, creating favorable living conditions. That is why it is particularly important to apply nature-compatible solutions for climate adaptation in the Curonian Spit area.

II. Research methods

The study employed field observations, modeling, and a monographic method. The InVEST Urban Stormwater Retention Model from the InVEST software suite was used to assess the annual volume and quality of stormwater. This model evaluates potential groundwater recharge and the amount of pollutants in surface runoff. [4]. The InVEST Urban Stormwater Retention Model primarily addresses surface runoff and is designed for implementation in urban watersheds. It calculates the annual volume and quality of retained stormwater, thus showing the prevention of pollutant transfer to water bodies. Retention, groundwater recharge, and surface runoff are evaluated on an annual scale rather than for individual adverse events. [2]. The model calculates the annual retention volume of runoff for the Curonian Spit National Park over an area of 0.1 hectares. Categorization of the results into three groups is used for clarity.

The initial data processing was carried out in two Geographic Information Systems – QGIS version 3.24.3 and ArcGIS ArcMap version 10.3. Maps and diagrams were developed in GIS ArcGIS ArcMap version 10.3.

III. Results

To identify areas on the Curonian Spit susceptible to climatic flood risks, a study on runoff retention was conducted. Runoff modeling identified critical areas for flow retention (marked in red in Figure 1). These critical areas are characterized by a low annual volume of flow retention, resulting in high flood risks. The study revealed that the village of Rybachy faces the greatest flood risk, with a retention volume of less than 220 m^3/year from an area of 0.1 hectares, while the annual runoff volume exceeds 276 m^3/year with a soil filtration coefficient of up to 44 m^3/year. The village predominantly consists of soils with high runoff potential, comprising 20-40% clay and 50% sand [5]. Based on these results, Rybachy is identified as the most flood-prone area, with a population of about 1,000 residents. The location of Rybachy is detailed in the Figure 2.

To modernize the drainage and rainwater collection system and minimize the climatic flood risks in Rybachy, nature-compatible solutions are proposed for integration into the existing infrastructure. Given the soil and climate conditions in Rybachy, bioswales and permeable parking lots are recommended for rainwater collection. Bioswales are vegetative stormwater systems that form part of a sustainable drainage system. They consist of specialized soil layers, gravel, drainage systems with perforated pipelines, and overflow mechanisms to manage substantial stormwater volumes. Bioswales will be placed in adjacent areas to collect water from roads, pedestrian surfaces, and roofs.

For flood protection, the use of wetlands is proposed. Treated water will flow through linear bioswales and drainage pipes to the wetland, which will serve as a site for wastewater accumulation and treatment. Artificial wetlands are engineered systems that enhance the physical, biological, and chemical processes of water purification. They are widely used for treating municipal wastewater, landfill leachate, urban stormwater, and industrial wastewater. Wetlands not only purify water (removing fine sediments and pesticides) but are also provide habitats for wildlife, enhance aesthetics, reduce flood risks, and facilitate water reuse. Artificial wetlands can be established in areas with high stormwater volumes.

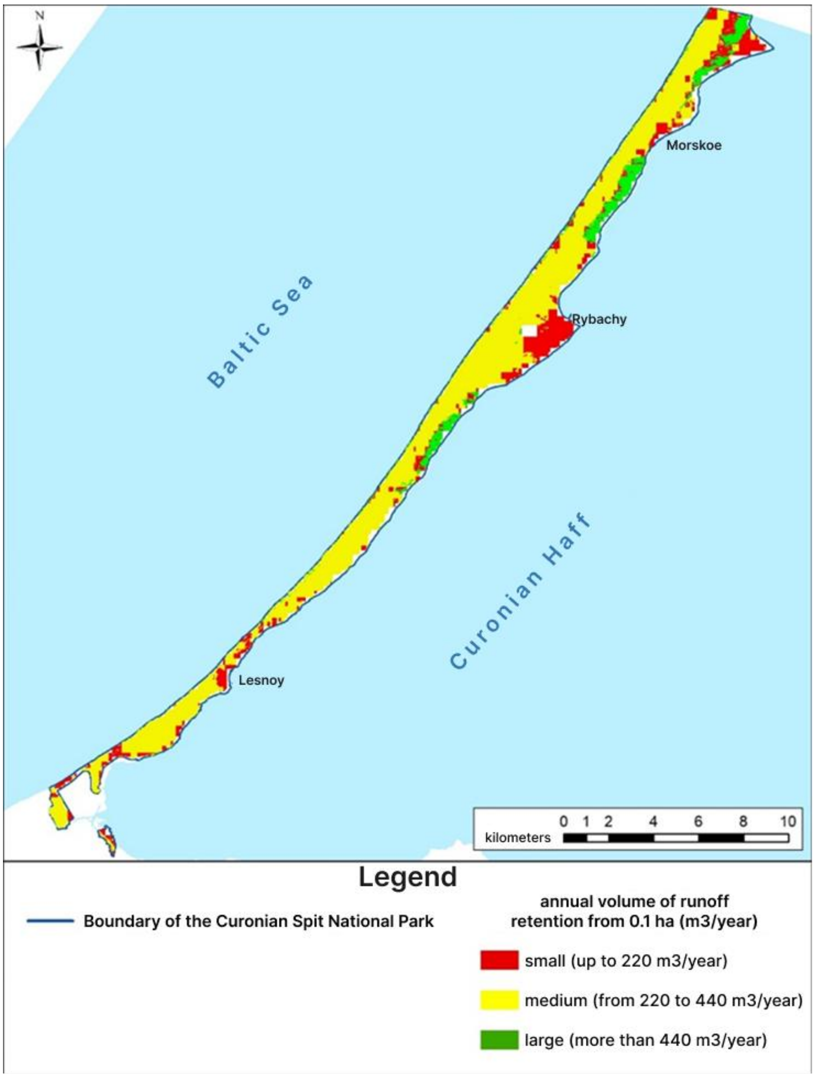

Figure 1: *Annual volume of runoff retention in the Curonian Spit territory*

Figure 2: *Area of the village of Rybachy*

Based on the studies in Rybachy, proposals were developed for the placement of bioswales, wetlands, and permeable parking lots (Figure 3).

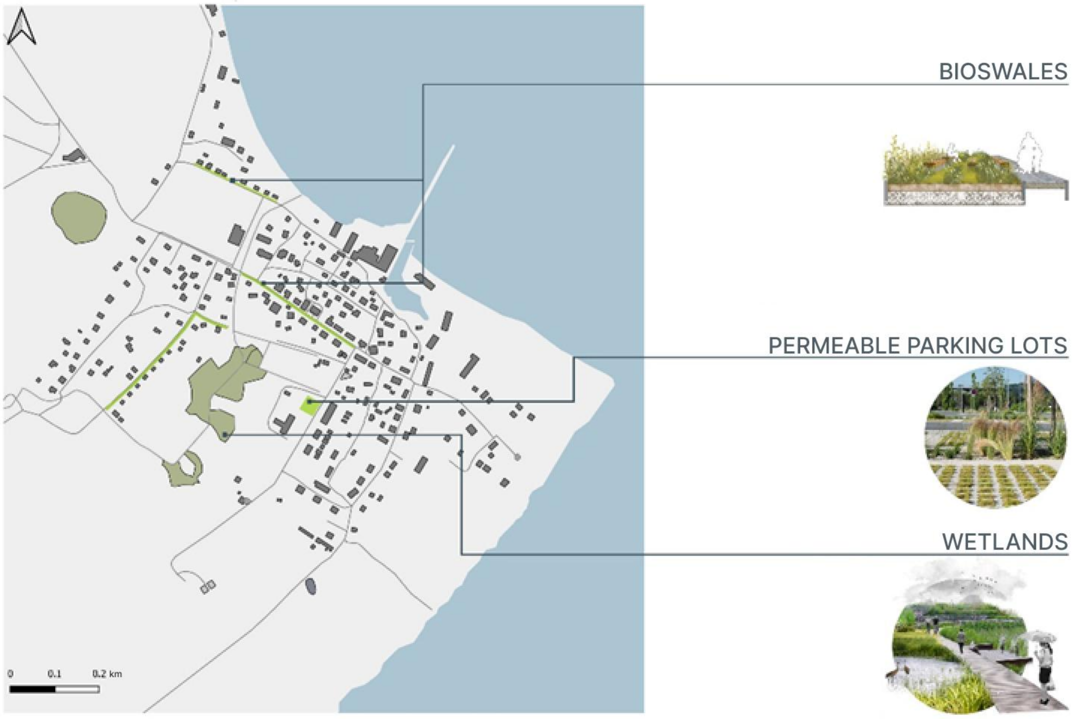

Figure 3: *Location of proposed nature-compatible technologies*

Modeling and international experience indicate that the most effective natural solution for the study site is the establishment of wetlands (Figure 4).

Figure 4: *Location of the proposed wetlands*

Bioswales are to be created along roads. These bioswales will be installed along the transition zone, with the covering made at an incline for natural water drainage into green islands At the same time, water entering the bioswale undergoes natural purification due to the vegetation layer, with sand acting as an absorbent and layers of gravel and geotextiles providing filtration. In other words, bioswales are multifunctional stormwater transport systems capable of retaining excess water and filtering out dirt and pollutants. The proposed locations for bioswales are shown in Figure 5.

Figure 5: *Location of the proposed bioswales*

The implementation of these nature-compatible solutions in Rybachy is expected to reduce climatic flood risks due to water retention in the wetlands. The volume of filtration directly in the wetlands and bioswales is projected to be more than 440 m^3/year, with more than 220 m^3/year retained in the village (Figure 6).

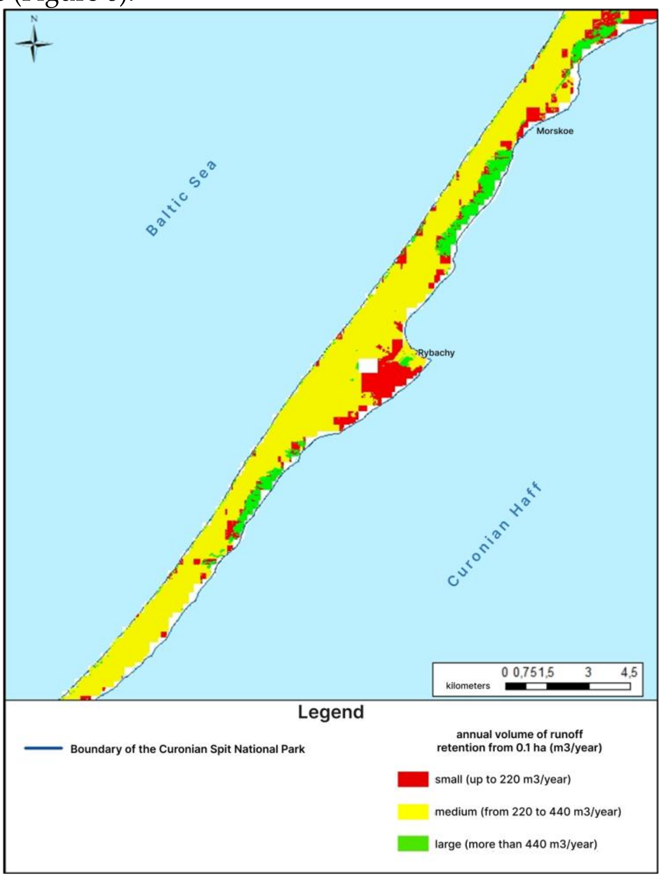

Figure 6: *Annual volume of flow retention in the Curonian Spit after the implementation of nature-compatible solutions*

IV. Discussion

The effectiveness of such solutions is well-documented internationally. In New York, there are over 5000 wetlands that provide wildlife habitats, absorb atmospheric carbon dioxide, enhance settlement resilience to climate change, reduce flood risks, and collect, retain, and filter stormwater.

V. Conclusions

Research conducted in Rybachy highlights the importance of nature-compatible solutions in minimizing climatic flood risks on the Curonian Spit. The arrangement of bioswales, permeable parking lots, ha and artificial wetlands will mitigate flood risks and modernize the rainwater drainage and collection system in Rybachy.

Modeling results show that the introduction of nature-compatible solutions reduces the flood risk by 50%, and double the volume of retained runoff. The implementation of the proposed solutions will increase the filtration volume in the wetland site from 44 m^3/year to 86 m^3/year per 0.1 hectare and raise the volume of retained stormwater to 440 m^3/year per 0.1 hectare.

In addition, the creation of artificial wetlands plays a crucial role in restoration ecology. Many wetlands are among the most productive natural ecosystems, often surpassing the best farmland and rivaling the productivity of tropical rainforests. They provide habitats for a rich diversity of native species, thereby preserving biodiversity and minimizing the risk of ecosystem destruction. Bioswales effectively treat rainwater, reducing pollutants, providing attractive wildlife habitats, and naturally replenishing groundwater reserves.

ADAPTATION OF THE HOUSING AND UTILITIES SECTOR OF BELARUS TO CLIMATE CHANGE

Lubov Hertman

•

Belarussian State University, BELARUS
lubov.hertman@yandex.by

Abstract

The article is devoted to assessment of impact of climate change on activity of housing and communal services sector in the Republic of Belarus. Assessment of climate change impact, risks and opportunities of housing and communal services sector was carried out on the basis of qualitative and quantitative analysis of sectoral «impact chains». Climate change impact assessments were carried out for water supply and sanitation (sewerage), rainwater sanitation. Heat waves, intense heat, droughts will have a significant negative impact. Warming in winter will have a positive impact on wastewater treatment. Based on the findings, a strategy for adapting the housing and utilities sector to climate change is currently being developed.

Keywords: housing and utilities sector of Belarus, climate change, adaptation measures

I. Introduction

In accordance with the National Strategy for Sustainable Socio-economic Development of the Republic of Belarus until 2030 [1], the main measures to reduce the impact of climate change on socio-economic development are:

- increase the ecological security of the territories by optimizing the location of production facilities and the organization of territories of settlements;
- modernization in the main industries;
- establishment of a natural risk management system;
- introduction of water-saving technologies;
- creation of reliable hydrometeorological monitoring and others.

The development of the «green» economy in Belarus implies solving environmental problems while ensuring economic security, social stability and creating additional conditions for the resumption of sustainable economic growth.

In many sectors of the economy there are real needs for the modernization of technological processes, the introduction of innovative «green» technologies that allow to increase the ecological sustainability of the economy and increase employment of the population by improving working conditions, and ample opportunity to do so.

Taking into account socio-economic conditions, prospects, expediency, international obligations, priority directions of development of «green» economy in the Republic of Belarus [2] include the following:

- implementation of sustainable consumption and production;
- development of the closed cycle economy (circular economy);
- formation of smart and energy efficient cities;
- development of electric transport (infrastructure) and urban mobility;
- climate change mitigation and adaptation.

These areas of development of the country’s economy in the context of climate change are directly related to the living conditions of the population, which supporting by housing and communal services.

Therefore, assessing the impact of climate change, vulnerability and climate risks in the housing and communal services sector in order to strengthen the planning system for adaptation to climate change in the Republic of Belarus is an important task at the present stage. The research was carried out within the framework of the project «EU for climate» in 2021-2022 with the financial support of the European Union (EU) and is implemented by the UN Development Programme (UNDP).

II. Methods

For the purposes of this study, the following activities of the housing and communal services are considered: drinking water supply and sanitation (sewerage), rainwater sewerage. The objects of the study are elements of engineering infrastructure and provided services of water supply and sanitation. The assessment also took into account the conditions of water supply and sanitation for urban and rural settlements, including water supply and the collection and treatment of domestic and surface wastewater from industrial plants.

Assessment of climate change impact, risks and opportunities of housing and communal services industry was carried out on the basis of qualitative and quantitative analysis of sectoral «impact chains». To identify the focus of priority adaptation measures to climate risks, information is needed on the difference in the magnitude of such risks in the spatial (e.g., regional/district) or temporal (current - future) dimensions. The standardized risk assessment methodology of the German Society for International Cooperation (GIZ) [3] was used for this purpose.

According to the GIZ methodology, the risk is divided into three main components: «exposure», «vulnerability» and «hazard», each of which is assigned its own weight and a set of indicators with their thresholds and its own weights. A numerical value is then calculated for each risk component, taking into account rationing of indicators. On the basis of the values of the risk components, the integral risk indicator for the examined system is calculated.

For example, the forecasting of future risks of disturbance of treatment facilities and risk of contamination of surface water bodies was carried out taking into account information about climate change and parameters of the system. The «exposure chain» for the risk of disruption of the operation of treatment plants with a set of indicators for each component of the given risk is presented in Fig. 1.

The «Hazard» component includes an increase in hot and very hot days, average annual rainfall and the duration of winter.

For the component «Exposure», two indicators have been selected: the number of cases of excess pollution of water bodies by wastewater and the coverage of the population by water treatment and wastewater treatment systems.

For the risk component «Vulnerability» four indicators were selected: two describe sensitivity («deterioration of water treatment infrastructure and facilities», «number of water bodies with poor and very poor ecological status»), and two describe adaptive capacity («developed national documents and technical standards» and «percentage of biological treatment plants»).

Analysis of sectoral «impact chains» allowed to determine the main risks, necessary measures and resources for adaptation of housing and communal services industry.

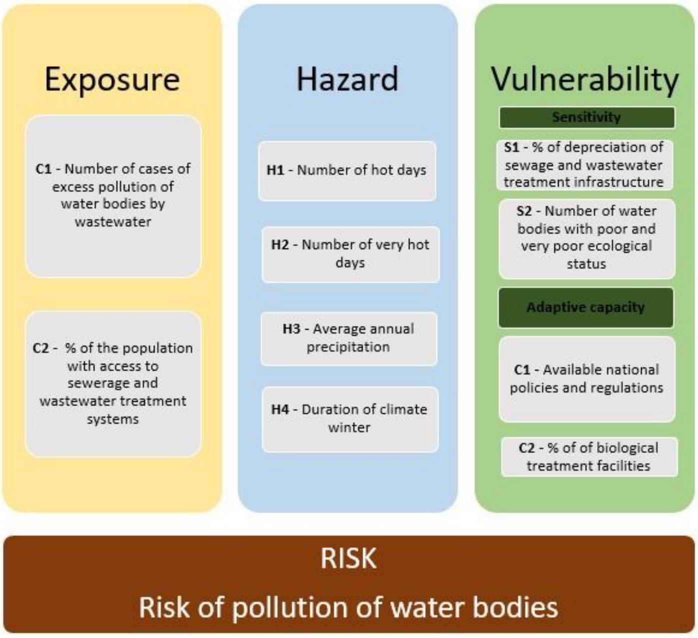

Figure 1: *«Exposure chain» for risk of disruption of treatment plants*

III. Results

The low impact of climate change on water supply is due to the use of groundwater for drinking water supply - the central water supply uses deep aquifers that are less susceptible to weather conditions. However, additional water will be required during hot periods, increasing pressure on infrastructure. The impact of climate change is most significant for areas not covered by central water supply, due to the reduction of water availability in the first aquifers from the surface during hot periods, especially during long heat waves. For regions where water is supplied from surface water bodies, the probability of not only decreasing water supplies but also polluting water sources increases during hot periods. Additional resources will be required to compensate for water shortages (water supply) and water treatment. In the case of heavy rains, there is a possibility of flooding and flooding of the water treatment and water supply infrastructure, especially in flood plains. Additional problems may arise due to the use of infrastructure with an excessive service life under increased loads during hot and heavy rains.

The impact of climate change on sanitation (sewerage) is both positive and negative. On the one hand, it is possible to reduce the cost of pumping, maintaining the required wastewater temperature, treating wastewater by increasing the length of the warm period and reducing the number of cold days. On the other hand, additional efforts will be needed during hot days and «heat waves» to maintain biological wastewater treatment processes. In addition, increased wastewater treatment costs will be required during a period of reduced water consumption and dilution capacity in watercourses. Additional problems may arise due to the use of infrastructure with an excessive service time under increased loads during hot and heavy rains. Higher temperatures lead to increased fermentation of solids in mud, resulting in an unpleasant odor. Harzards can lead to additional costs to eliminate leaks from municipal liquid waste storage systems in regions without a central sewerage system, additional costs for the export of sewage by special vehicles.

Treatment of wastewater to bring it up to the required quality parameters becomes technologically more complex and expensive due to higher temperatures, increasing and changing pollutant concentrations in the effluent. Heavy rains can cause flooding and disruption of sewage treatment plants through sewage maintenance.

Table 1: *Expected impact of climate change on processes and systems in housing and communal services in Belarus*

Parameter	Trend	Industry Processes and Systems			
		water intake	water treatment	water and sewerage system	wastewater treatment and collection

Hard frost	↘			● moderate, mixed	● moderate, positive
Strong wind	[↘4]				● moderate, positive

Expected impact of these climate trends: ● strong ● moderate
direction of the impact: ● negative ● mixed ● positive

[ ] No forecast due to significant variability, analysis based on current trends
1 Above world average, especially fast in the summer-autumn period
2 Especially winter time
3 Uneven between seasons and areas, particularly vulnerable south-east of Belarus
4 Uneven across regions

The distribution of rainfall is the determining factor for rainfall. The main condition for the operation of rainwater is the intensity (supply) of rain and fluctuation of water level in water bodies. The most problematic are heavy rains in summer, causing flooding and flooding, destruction of water supply infrastructure and wastewater treatment.

The risk to the housing and utilities subsystems is due to changes in precipitation patterns (frequency and intensity of rainfall) and temperature factors (high air temperatures, frequency, duration).

In general, slow climate change may have a positive impact in terms of reducing the costs of certain winter processes (pumping and treatment of wastewater)However, droughts and long periods of heat will require additional efforts and costs to provide consumers with additional water, water treatment, water transport, etc. Extreme events, such as heat waves and heavy rains, can be particularly damaging.

IV. Discussion

Adaptation measures to climate change (Table 3) can be divided into:

- “soft” (including institutional and behavioural (related to educational processes, behavioural change), regulatory (i.e., in terms of law-making, regulatory legal framework, including technical normative legal acts, etc.), planning (related to the collection and use of climate information, territorial development, sectoral development programmes),
- “grey” (infrastructure) (related to the operation and construction of infrastructure, technological

processes and services),
- "green" (related to the use of natural solutions and the development of water-green infrastructure).

Table 2: *Expected impact of climate change on housing and communal services in general*

4 Uneven across regions

Belarus has a system for monitoring surface and groundwater quality. However, additional measures are needed to strengthen the monitoring system for groundwater and surface water bodies. Monitoring may also include modelling aspects to predict the availability of groundwater and changes in groundwater and surface water quality.

Studies to quantify the impact of climate change on groundwater and surface water, as well as on components of the water supply and sanitation system, taking into account the current infrastructure situation and projected climate change indicators, are relevant.

Information and education activities will raise awareness of stakeholders on the impact of climate change on water supply and sanitation. In addition, timely clarification of adaptation to climate change at different levels will increase the motivation of both residents and decision makers to apply adequate measures for the industry in response to climate change. The concept of improvement and development of housing and communal services until 2025 includes measures to improve the quality of training, retraining and advanced training of specialists in housing and communal services. Cooperation with citizens and organizations should also be strengthened. Outreach activities may also include information on problem areas, pollution prevention, flood and flooding prevention, operational telephones and others.

Planning the development of the industry taking into account expected climatic changes will reduce risks to the normal functioning of water supply and sanitation networks and services. Long- and medium-term planning involving all stakeholders to ensure a balance between demand and supply of quality water.

Resources and capacity to develop and implement adaptation measures	🟡	🟡	🟢	🟡	🟢	🟢	🟡	🟢	🟡

◎ Adaptation measures are needed
🟢 Sufficient resources and capacity to develop and implement measures
🟡 Limited resources and capacity to develop and implement measures
🔴 Resources and capacity to develop and implement measures are scarce
C - "grey" activities; 3 - "green" activities; M - "soft" activities

Improvement of regulatory legal framework, including technical regulations, in terms of design standards (especially for «long-lived» facilities), ensuring the capacity of new networks, The improvement of requirements for the design and construction of treatment plants, technologies and cleaning methods, taking into account modern technologies and changing climatic conditions, will increase the efficiency of the system.

Surveys of the technical condition of networks and structures, maintenance allows to maintain maintained networks and installations in proper technical condition. However, the funds for repairs and replacement of equipment are only for minimal activities. As temperatures rise, extreme weather events (showers, heat waves, flooding) the cost of maintaining networks increases. Network maintenance programmes may need to be adjusted, including increasing the frequency of maintenance, additional provisions for wastewater treatment, etc.

Technical re-equipment of infrastructure facilities and improvement of their efficiency includes construction of new infrastructure, modernization of structures to increase efficiency and level of treatment of raw water and wastewater, to reduce their impact on the environment and public health.

Water demand management and conservation measures aim to strengthen and support existing mechanisms and practices to reduce water use. These measures may include both information and education and infrastructural measures aimed at the reuse of water.

The land management system provides for the restoration of ecosystems, the establishment and maintenance of borehole sanitary zones, the restoration of green vegetation, etc.

The implementation of programmes and strategies for the development of housing and communal services and related industries, aimed at the development of the industry, will reduce vulnerability and dependence on climate change.

Based on the findings, a strategy for adapting the housing and utilities sector to climate change is currently being developed.

[2] The Graduate Center City University, New York, USA
lia.matchavariani@tsu.ge

Abstract

A phenomenon triggered by modern global warming is a change in the freshwater balance between the land and the ocean in favor of the latter. Centuries-old reserves of mountain glaciers, ice sheets, and groundwater are moving into the oceans. The consequences of this event are particularly severe for regions with limited water resources, where the most optimal ways of solving the problem are designing new methods to calculate water balance and water consumption, modernizing and rationalizing the existing methods, and essentially prolonging the period of operation of water reservoirs. For this purpose, this study proposes a new method that makes it possible to extend the service life of a reservoir, significantly increase the accuracy of water balance operations, and efficiently use the accumulated sediments as a natural resource. This method was made possible through the use of the results of natural experiments on small mountain reservoirs, the generalization of research data on the dynamics of silting prisms of operational reservoirs, and the use of monitoring materials of river sediment. Methods of mathematical statistics (least squares, mathematical expectation, analogy), as well as methods to calculate the basic hydrological characteristics and the water balance of the reservoir, were used to generalize the information and analyze the research data.

Keywords: water balance, silting prism, mead reservoir, Colorado River

I. Introduction

Ongoing climate fluctuations are changing the freshwater balance between the land and the ocean in favor of the latter. Centuries-old reserves of mountain glaciers, ice sheets, and groundwater are moving into the oceans. The flow of glacier-fed rivers is increasing, while the flow of the rivers with basins in areas lacking moisture is decreasing [1]. The results of monitoring the runoff of the Colorado and Rioni rivers in 1960-1990 [2-4] offer clear evidence of this fact (Fig. 1, 2).

The growing demand for regulated water and the tendency to decrease runoff has increased the importance of water reservoirs, which has led to a focus of scientists on studies related to the siltation of reservoirs and related problems [5-13].

The unfavorable trend of the spatial and temporal distribution of water resources leads to severe problems, an effective means of adaptation and solution to which is spatial and temporal regulation of river flow by reservoirs. However, besides offering numerous advantages, reservoirs also have disadvantages, including silting with sediments (sand, pebbles, gravel, etc.) and solid residues of coastal deformation, which is an irreversible process. The accumulation of these products in a reservoir forms a "silting prism," which reduces the reservoir conservation zone and causes progressing errors in the W=f(H) curve of water registration and distribution. This feature is particularly dangerous for large urban conglomerates and irrigation facilities located in regions with insufficient water supply. In the southern arid region of the United States, the Colorado River flow is used almost entirely for irrigation and municipal water supply. The waters of the Amu Darya and Syr Darya Rivers in Central Asia are distributed among users in such a way that the

Aral Sea, a lake fed by these rivers, has almost completely dried up and the region itself has become an ecological disaster zone. The main reason for this ecological disaster was the incorrect water-balance inventory of river flow and users' ignorance of the climatic decline of the flow.

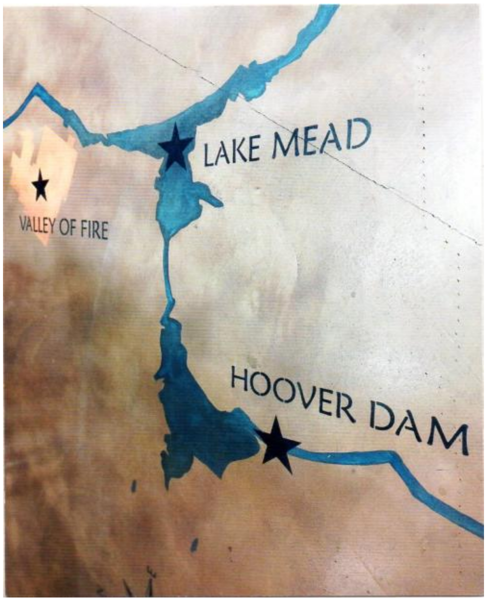

Figure 1: *Made reservoir on River Colorado*

B

Figure 2: *The trend of multi-year flow variability of (a) the Colorado River (North America) and (b) - the Rioni (Caucasus) in terms of current climatic conditions*

The economy of many regions of the planet is limited by the lack of regulated water volumes in the reservoirs, as the volumes decrease inversely proportionally to the increase of a silting prism. This factor clearly indicates that improving reservoirs' inventory and rational use is vital in the nearest future. The lack of regulated water resources hinders economic development in in many African countries and Australia. Consequently, improving the regulation and balancing of river flow is an important task for them as well.

Accordingly, the primary purpose of this research was to conduct studies of water balance, improve the accounting of balance elements, and design and modernize the calculation formulas. The objective of the study was formulated as follows after summarizing results: assessing the reduction of a reservoir conservation zone caused by a silting prism and designing methods for periodically correcting the curve *W=f(H)* and extending the service life of the reservoir.

II. Methods

The research employed mathematical statistics methods (least squares, mathematical expectation, analogy), as well as methods to calculate the basic hydrological characteristics and the water balance of the reservoir. For this purpose, field, and natural studies were conducted on reservoirs of different regulations and types in Georgia to study the silting processes in operating reservoirs, especially when the silting prisms were in the last phase of development. The studies were also conducted on small mountain rivers, where natural experiments to study the features of silting processes are highly efficient.

III. Results and discussion

Siltation of a reservoir is an ongoing, irreversible process that reflects the accumulation process of sediment in it, specifically of material resulting from bank formation and anthropogenic activity. The deposited material forms what is known as a silting prism, a body originating at the mouths of tributaries and constantly growing in all directions. It increases most rapidly forward, to the dam, and backward, and to the mouths of the tributaries. The main feature of the prism growth rate is its permanent increase at a decreasing rate. This value is maximum in the initial phase of reservoir operation and is minimum at the end of the third phase of operation when the silting prism reaches its maximum volume. In this phase, the surface of the silting prism is plain inclined toward the dam, whose gradient and other morphometric parameters are such that any tributary can completely carry the sediment to the tailrace. In this phase, the siltation process practically stops, and the volume of the silting prism significantly (1.3-1.5 times) exceeds the size of the reservoir, fills it completely, and emerges in the estuaries above it as a “tail” of the silting prism [14, 15].

The main feature of the reservoir is the movement of the water level between the dead volume level and the normal filling level. Due to this peculiarity, during the filling and emptying phases of the reservoir, the mouths of the tributaries constantly displace and distribute the sediment within the reservoir depending on such motion. Accordingly, the river-regulating reservoir is an object functioning for a certain time (T, year), whose efficiency is maximum in the first phase of operation, and minimum in the third, when it is filled and covered with sediment and has completely lost the ability to regulate the flow.

According to the field studies, the reservoir continually losses its volume, and the multi-year regulating reservoir is reduced first to a seasonally regulating reservoir, and then to one controlling only the daily flow.

During the silting process, sediment constantly accumulates at the mouths of tributaries and in areas surrounding their channels. As a result, the bed rises, the water conductivity of the tributaries decreases, and the probability of catastrophic floods increases drastically. In this state, the silting prism expands in the tributaries at a distance L_i determined by the initial slope of the river (I_0) and the diameter of the largest sediment (*dm*).

The volume of water accumulated in a reservoir is measured and regulated by type *W=f(H)*, the so-called working curve, reflecting the dependence between the water level (*H*, cm) and the volume (*W*, m^3) accumulated in the reservoir. The drawback of such a dependence is that if it is not periodically corrected, an error that equals this prism value (W_0) and increases proportionately to it emerges in the operation of any hydraulic facility. This property of a prism necessitates periodic correction in the working curve according to the data of geodetic planning of the prism or results of the water-balance survey. This peculiarity of the reservoir should be considered during its design, that is, in the selection of the site and morphometric parameters, and the realization of the working curve *W=f(H)*.

Water supply in the reservoir is measured by the curve of dependence of water levels and volumes, which in practice is known as water balance or working curve *W=f(H)*. The volume of flooded water (*W*) depends on the water content of tributaries and the water consumption value (*P*), which vary from year to year and from season to season. The reservoir water balance is used, which is mathematically expressed by the following equations, to study spatial and temporal variability:

$$\Sigma G - \Sigma P = \Sigma A \pm H \quad \text{(filling phase), and}$$
$$\Sigma P - \Sigma G = \Sigma A \pm H \quad \text{(discharge phase)} \qquad (1)$$

Here: *G* represents the components of the inflowing portion of the water balance (flow of tributaries, sediments on the water level, groundwater, etc.); *P* denotes the components of the outflowing portion of the water balance: water consumption for electrical power, irrigation, utilities, and evaporation; A is the change in water volume in the reservoir, which is calculated by the water working curve; and *H* is the balance error.

The component *H* in Equation 1 is a random variable called the balance accuracy index. It is a random variable as long as all balance components in Equation 1 are written with acceptable accuracy. Its value varies from years to years and seasons to seasons; that is, it is sometimes positive (H≥0), and other times negative (H≤0). The balance accuracy for any period is satisfactory if

$$\frac{\Sigma G}{H} \leq 15\% \text{ (filling phase)} \quad \text{and} \quad \frac{\Sigma P}{H} \leq 15\% \text{ (discharge phase)} \qquad (2)$$

H maintains this property until new factors turn it into a constant, increasing value. A similar permanently increasing factor is the volume of a silting prism, which increases in proportion to the accumulated solid sediment. This process stops only when the volume reaches a limited and the tributaries produce stable hydrographic curves.

Accordingly, the transformation of the component *H* into a constant value occurs as a result of the annual accumulation of sediment of volume R_i and product in the amount of N_i formed during the deformation of the reservoir banks. Hence, in the first phase of reservoir operation, that is, after *n* years, it does not exceed the permissible error of water balance (2), when their volume is

$$M = \sum_i^n (Ri + Ni) \qquad (3)$$

In the second phase of reservoir operation, after *m* years (mn) the accumulated solid material forms a prism of volume W_m. After that, the component *H* becomes an explicitly increasing value, and the curve *W=f(H)* changes its position and shape (Fig. 3).

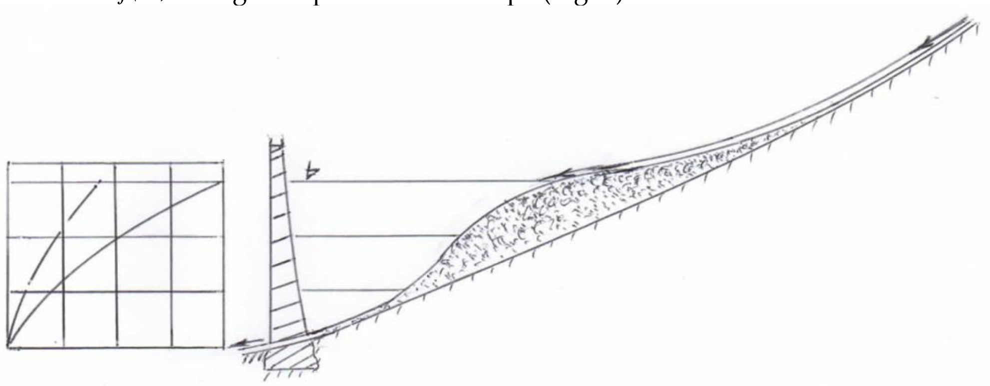

Figure 3: *Longitudinal sections of the silting prism of a reservoir in different phases of prism formation and the corresponding state of the curve W=f(H)*

In the third phase, the tributaries consume most of the sediment to form their bed slope and other morphological parameters and carry an increasing amount of sediment from the reservoir to the tailrace. At the end of this phase, the reservoi's conservation zone is almost completely covered with silting prism material, and the tributaries have transported all the sediment to the tailrace. In this phase, the *H* member of the balance exceeds the reservoir conservation zone, and the working curve has the corresponding shape.

Any operation aimed at managing the accumulated water requires an appropriate monitoring system. If there is no such system provided for a reservoir, an approximate correction of the curve W=*f*(H) is possible by the average volume of solid sediment in the tributaries ($\frac{1}{n}\sum_{I}^{n} Pi$). Such information is a necessary component of the reservoir design parameters and is not difficult to obtain. The corrected, that is, the approximate value of accumulated water volume A_i, can be calculated using the following expression:

$$A_i = \sum\nolimits^{n}_{j} A - \sum\nolimits^{n}_{jPi}, \qquad i = 1,2,..n \qquad (4)$$

A geodetic-bathymetric survey method is designed to avoid gross errors in water balance accounting and planning and in, related losses. With its program, a grid of reference points should be constructed, which includes a reservoir basin at the normal flooding level. The grid density depends on the morphometric and terrain peculiarities of the basin. It is advisable to conduct the survey in the season of the year when the water level is the lowest, as the land survey data are more accurate than the bathymetric data.

For the cross-sections fixed by the reference points, the cross-sections of the reservoir must be plotted with the hypsometric data taken from the design map of the reservoir basin (Fig. 5) showing the state of the terrain of the basin before flooding. Land and bathymetric surveys must be plotted in each section. The portions of each two bordering sections covered with sediment will form a geometric figure, the approximate shape of which is a prism or pyramid. The volume of such figures is calculated using well-known mathematical expressions:

$$V_i = sh \quad \text{(prism)} \qquad (5)$$

Here, w_i is the volume of portions between the silting prism sections, m^3; h is the distance between the bordering sections, m; and *s* is the area of the silted figures, m^3

$$V_j = \frac{1}{3}\left(s + \sqrt{sp} + p\right)h, \quad \text{(truncated pyramid)} \qquad (6)$$

Here, V_j is the volume of the portion between the silting prism sections $\{V_j\}^{m}_{j=1}$, (in m^3), and ; *s* and *p* are the areas of the lower and upper bases of the pyramid (in m^2). The areas of silted areas with complex geometry, not resembling any known geometrical figures, can be calculated with a planimeter.

The values *Vi* and *Vj* of *n* sections of the silting prism form three information groups. One of them unites the discrete volumes of prismatic bodies (V_i). The second contains the values of pyramidal bodies (V_j), and the third contains the results of planimetry (V_f):

$$\{V_i\}^{k}_{i=1}, \ \{V_j\}^{m}_{j=1}, \text{and } \{V_f)^{p}_{f=1}\}, \text{ where } i=1,2\,3,\dots k;\ j=1,2,3,\dots m, \text{ and } k+j=n \qquad (7)$$

The total volume of the silting prism is the algebraic sum of the values calculated above:

$$W = \{V_i\}^{k}_{i=1} + \{V_j\}^{m}_{j=1} + \{V_f)^{p}_{f=1}, \text{ where } k+j+f=n \qquad (8)$$

According to Equation 8, $W_1 = f(H)$, *a* corrected version of the curve *W=f(H)* will be constructed.

The frequency *τ* of such operations is determined by the relation of reservoir volume (*W*) to the annual volume of solid matter deposited in it (*ω*), that is, the frequency of curve correction is proportional to the folowung ratio.

$$\varepsilon = \frac{W}{\omega} \quad (9)$$

Generalizing the study results during the critical low-water period of Colorado reservoirs (1970-1990) for analysis and efficient recommendations is an urgent task. It is also interesting as such critical situations are numerous and their number is increasing in the arid regions of the world (Fig. 4).

Figure 4: *The water level of Mead Reservoir (Lake) in 2023*

The Colorado River flow (Table 1) is regulated by three large and several small reservoirs (Table 2). These reservoirs supply irrigation and municipal water to the states of California, Arizona, and Nevada, as well as the cities of Las Vegas, Los Angeles, and San Diego [7]. These cities consume ~1.0 km^3 of water per year, while the states are much heavier and more extensive (21.6 km^3) consumers of irrigation water. The average volume of annual sediment of this river is ~145 million tons. With water flooding in the reservoir starting in the spring of 1935, the volume of the silting prism produced in the reservoir is expected to have reached 12.6 billion tons by 2020.

Consequently, due to siltation, the reservoir had already lost 34% of its volume by 2020, most of which (80-85%) was useful volume. During this period, the volume of the Mead Reservoir decreased to 23 km^3. If, based on this information, the curve W=f(H) of the reservoir were not corrected periodically, the measurement and consumption of the accumulated flow would be recorded with incremental errors, the size of which has reached ~12.6 km^3 at present. These studies show that when the silting prism ignores the permanent reduction of useful water volume and this process develops against the background of flow reduction caused by current climate change (Fig. 1), the water balance of the regulated flow and water consumption proceeds with ever-increasing errors.

Table 1: *Colorado River Basin Water Balance*

Basin area, thous. km^2	Atmospheric precipitation, P		Runoff, Q		Evaporation, E		Balance mismatch H=P-Q-E		Runoff coefficient $k=\frac{Q}{P}$
	mm	km^3	mm	km^3	mm	km^3	mm	km^3	
635	377	239	$\frac{36}{0.24}$	$\frac{23}{0.15}$	$\frac{258}{294}$	$\frac{164}{187}$	83	22	0.10 0.0

Numerator: flow balance before the construction of the reservoirs;
Denominator: flow balance during the operation of the reservoirs

Table 2: *Morphometry of Colorado River reservoirs*

Water reservoir	Start filling, year	Normal inflow level, m asl	Morphometry					
			Volume W, km^3	Area F, km^2	Depth, m	Length, m	Regu-lation	Usage
Powel, Australia	1964	1174	33.3 25.7*	658	179.5	300	Multiyear	Flood; Irrigation; Communal supply; Energy sector; Navigation.
Mead, US	1935	368.7	36.8 33.5*	640	162	185	Multiyear	Flood; Irrigation; Communal supply; Energy sector.
Mohave, USA	1951	214	0.25	10.7	197	74.1	Annual	Irrigation; Energy sector; Communal supply.

(* Useful water volume)

It is impossible to prevent the process of silting of reservoirs, especially of those regulating river flows. However, it is possible to considerably increase their service life. For this purpose, a system of sediment collection quarries should be provided in the area of displacement of the curve of reservoir flooding and in the mouths of tributaries.

The sediment collection system captures most and the largest fractions of sediment during floods and flash floods. Sediments from these quarries can be used for construction, to fill degraded coastal beaches, to increase the service life of reservoirs, and for other purposes. The operation of such quarries will greatly reduce the heavy burden on nature caused by the extraction of inert material (sand, pebbles, and gravel).

IV. Conclusions

- Permanently decreasing flow regulation capacity of reservoirs is inevitable due to the growth of the silting prism and modern climate warming.
- The operations using the $W = f(H)$ curve, if the curve is not periodically corrected according to the silting prism size, contain increasing errors, which is particularly problematic in arid regions with great water consumption.
- In case of a shortage of regulated water resources, the accuracy of water balance and water consumption operations in the reservoirs must be improved significantly.
- The proposed method is the first attempt to increase the safety of the population in the mouths of tributaries, reduce the pressure on nature caused by sediment removal from river beds, and increase the volume and reliability of inert material supply.
- Water consumption problems in the near future make it urgent to extend the lives of reservoirs and launch sediment collection quarries.

Abstract

The article examines the importance of international agreements and treaties in addressing climate change. Global warming is a transboundary problem and no country can address it alone, which highlights the need for cooperation through international frameworks. The article covers key agreements such as the Paris Agreement, the Kyoto Protocol and the United Nations Framework Convention on Climate Change (UNFCCC). These initiatives aim to reduce greenhouse gas emissions, increase resilience to climate change and promote sustainable development. The author focuses on the difficulties of achieving international consensus due to differences in economic status, national interests and political conflicts between countries. Important considerations include mechanisms for monitoring the implementation of commitments, financing climate programs and technology transfer to developing countries, which helps them adapt to changes and reduce their own emissions. Particular emphasis is placed on the need to increase ambitions for emission reductions to keep global warming within 1.5°C. The article also notes the role of civil society, non-governmental organizations and the private sector in promoting and supporting the implementation of international climate commitments, as well as the need for their active involvement in decision-making and the implementation of climate policy.

Keywords: climate change, global warming, international agreements, greenhouse gas emissions, sustainable development, climate resilience

I. Introduction

Over the past few decades, the center of gravity in environmental diplomacy has confidently shifted towards the issue of climate change. The visible effects of climate change are apparent: familiar weather patterns are changing across various parts of the world, glaciers and snow caps are melting, sea levels are rising, and the frequency of extreme weather events is increasing. "This is not surprising," scientists say, "because climate change is a natural cyclical process influenced by numerous natural and geophysical factors. It has been this way for billions of years and will continue to be in the future." However, it is alarming that, according to a fairly widespread opinion within the scientific community, the main cause of climate change, specifically global warming, over the past 50 to 100 years has been the increase in the concentration of greenhouse gases (GHGs) in the atmosphere due to the growing volumes of human economic activity.

At the turn of the 1980s and 1990s, when ecology made a significant breakthrough into mainstream politics, the issue of climate change began to gain increasing international resonance. It was actively embraced by international organizations, and in 1988, the Intergovernmental Panel on Climate Change (IPCC) was established under the auspices of the UN. The IPCC started to release assessment reports on the state of the planet's climate approximately every four to five years. With each report, experts' conclusions became more confident: the trend of warming on Earth is occurring and has been largely explained by anthropogenic causes over the past century. According to the latest IPCC report in 2007, if current economic development scenarios remain unchanged, the climate could warm by more than 6°C by 2100, and sea levels could rise by nearly 60 cm. The world is threatened with an increase in natural disasters and extreme weather events, shifts in traditional agricultural and fishing zones, loss of biodiversity, and the flooding of entire cities and even countries.

In 1992, the UN Framework Convention on Climate Change (UNFCCC) was signed at the UN Conference on Environment and Development in Rio de Janeiro. In 1997, the Kyoto Protocol to this Convention was adopted in Kyoto, Japan, obligating 39 countries (from the category of industrialized nations and economies in transition) to reduce their GHG emissions by a total of 5.2% during the first commitment period (2008-2012) compared to 1990 levels. The Protocol entered into force in February 2005, thanks to its ratification by Russia.

In the second half of the 2000s, the intensity of discussions surrounding climate change in global politics reached its peak. Authoritative analytical centers recognized climate change as the number one threat to international security, surpassing even the threat of terrorism. In 2007, the UN Security Council devoted a special meeting to climate change for the first time. UN Secretary-General Ban Ki-moon began the practice of holding UN climate summits in the lead-up to the annual sessions of the UN General Assembly starting in 2007. Additionally, the IPCC, along with prominent American environmental politician Al Gore, was awarded the Nobel Peace Prize in 2007.

However, the rise of climate change as a global issue had its downsides. Over the past 20 to 30 years, the discussion surrounding global climate change has become excessively politicized, increasingly moving away from its scientific basis and often falling prey to political interests and speculation. Disagreements persist among scientists regarding, firstly, the extent of the influence of anthropogenic factors on climate change, and secondly, the optimal strategies for humanity to respond to this process. The scientific community has split into "alarmists," who emphasize anthropogenic causes of climate change, and "skeptics," who do not consider these causes to be decisive. Both camps include authoritative scientists with substantial scientific arguments and many reasons to criticize their opponents. Meanwhile, amidst such scientific confrontation, deliberately fueled by the media, politicians face the challenging task of choosing the only correct solution. Are these scientific disagreements not the root cause of the slow progress in international climate negotiations?

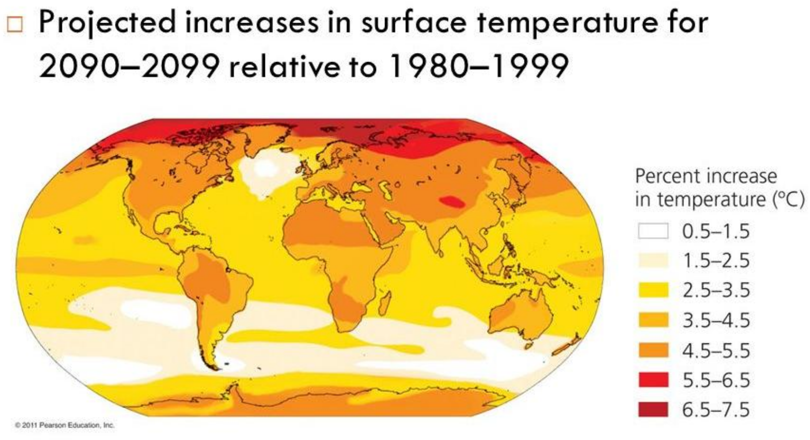

Figure 1: *The Earth's climate system*

Climate change has become one of the most pressing global challenges of the 21st century (fig.1). Rising temperatures, extreme weather events, sea-level rise, and shifting ecosystems are increasingly threatening human life, natural systems, and global economies (fig.2). The scientific consensus is clear: human activities, particularly the burning of fossil fuels and deforestation, are driving unprecedented levels of greenhouse gas emissions, leading to global warming. This issue, however, transcends national borders, making it impossible for any single country to tackle the problem in isolation. Addressing climate change requires collective action and a coordinated response from the international community.

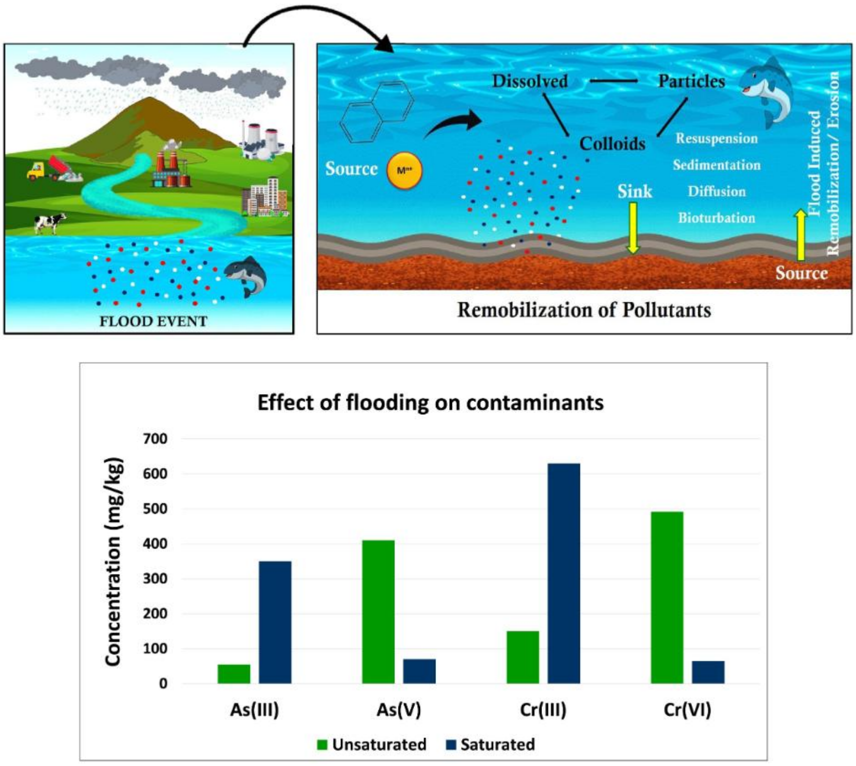

Figure 2: *Remobilization of contaminants during extreme flood events. While arsenic is more mobile and bioavailable under reduced conditions, chromium biomes less mobile and bioavailable*

Climate change significantly exacerbates the severity and frequency of wildfires, leading to a cascade of effects on soil properties and the broader ecosystem. These wildfires alter biological, chemical, and physical aspects of the soil, impacting soil organic matter and its structure, which in turn influences processes like soil erosion and metal transport. Increased temperatures can change the composition of organic matter, with destruction occurring at temperatures between 600°C and 700°C. This degradation of organic matter can further impact soil health and its ability to support vegetation. Climate change-induced erosion increases the transportation and migration of metals within the soil, leading to the loss of metals that are bound to humic materials and facilitating their release into the environment. Research by Frogner-Kockum et al. (2020) highlights how erosion exacerbates this issue. Furthermore, climate change can remobilize legacy metals, such as mercury, altering their release and conversion processes. For instance, mercury can be transformed into methylmercury, a more toxic form that is readily absorbed by organisms. Changes in the redox state of the soil due to flooding can significantly affect the mobility of various metals. Under unsaturated conditions, arsenic (As) exists primarily as the less mobile As(V) species, while chromium (Cr) exists as the more mobile Cr(VI) species. However, flooding can reduce As(V) to the more mobile As(III) and convert Cr(VI) to the less mobile Cr(III). These transformations impact the bioavailability, toxicity, and transport of these elements in soil and aquatic environments, leading to potential environmental contamination. Additionally, altered rainfall patterns due to climate change can significantly affect net carbon release from the soil. Low rainfall conditions lead to droughts, causing increased release of nitrous oxide (N_2O) from natural soils and inorganic carbon from carbonates and bicarbonates. Moreover, methane (CH_4) and carbon monoxide (CO) can be released from acidic soils (IPCC, 2019). The interplay between climate change, wildfires, and soil dynamics presents a complex web of environmental challenges. Increased wildfire frequency not only alters soil properties but also enhances the mobility and toxicity of metals, contributing to environmental contamination. Changing rainfall patterns further complicate the carbon cycle, highlighting the urgent need for comprehensive strategies to mitigate these impacts and protect soil health and ecosystems.

International agreements play a crucial role in forming a unified approach to combating global warming. These agreements, such as the Kyoto Protocol and the Paris Agreement, provide a framework for countries to set emissions reduction targets, share technology, and cooperate on adaptation strategies. By fostering collaboration among governments, they create a platform for nations to commit to ambitious climate goals, while also addressing the varying capacities and responsibilities of developed and developing countries.

The evolution of these agreements reflects the growing recognition that a global response is needed to limit temperature rise to below 2°C, and ideally 1.5°C, above pre-industrial levels. However, despite these efforts, there remain significant challenges, such as ensuring compliance, financing climate initiatives, and balancing economic development with environmental protection. This introduction sets the stage for an exploration of how international agreements serve as the cornerstone in the fight against global warming, and the challenges they face in driving meaningful change across the globe.

II. Methods

To analyze the role of international agreements in combating global warming, the following methods were used in this paper:

1. Analysis of documents and international agreements:

The main method is a detailed analysis of the texts of key international climate agreements, such as the Kyoto Protocol (1997), the Paris Agreement (2015), and the documents of the United Nations Framework Convention on Climate Change (UNFCCC). These documents are considered in the context of their role in global carbon regulation, reducing greenhouse gas emissions and adapting to climate change. The analysis assesses the legal obligations assumed by the participating countries and the mechanisms for their implementation.

2. Comparative analysis:

To identify differences in approaches to solving climate issues, a comparative analysis of the Kyoto Protocol and the Paris Agreement was used. This analysis examines their principles, mechanisms and results in order to identify changes in the global climate agenda and the impact of these agreements on countries with different levels of economic development.

3. Methods of statistical analysis:

We used data from international organizations such as the Intergovernmental Panel on Climate Change (IPCC) and the World Meteorological Organization (WMO) to analyze the dynamics of greenhouse gas emissions, Earth's temperature, and other climate indicators. These data made it possible to assess the extent to which countries-parties to international agreements are fulfilling their obligations.

4. Qualitative interviews and expert assessments:

We collected opinions from climate policy experts, representatives of international organizations, and non-governmental organizations. Qualitative interviews provided additional information on the challenges that countries face in fulfilling their climate commitments and on opportunities to improve existing regulatory mechanisms.

5. Content analysis of media and public demand:

We also conducted a content analysis of publications in the global media and social networks reflecting public sentiment and demands for stronger climate action. This method made it possible to study the influence of civil society and the private sector on the formation of climate policy at the international level.

The use of these methods made it possible to conduct a comprehensive analysis of international climate agreements, assess their effectiveness and identify areas for further improvement of global climate policy.

III. Results

The global climate agenda today occupies a central place in the formation of a strategic vision for the future of civilization. It promotes the integration of the efforts of countries to achieve sustainable development goals and the creation of an international institutional framework for the analysis and development of joint solutions. Over the past decades, the climate agenda has become an integral part of global politics, despite the current economic crises and growing contradictions between countries on economic development issues.

One of the reasons for the continued relevance of climate issues is the public demand for action aimed at preventing climate change. Citizens demand that governments take more decisive measures to protect the environment and preserve the planet for future generations. In addition, increasing competition between countries and corporations for leadership in the creation of new "green" infrastructure and technologies stimulates the transition to more sustainable economic models. It is important to note the formation of a new worldview that rejects the old economic principles of making a profit at any cost in favor of the concept of sustainable development.

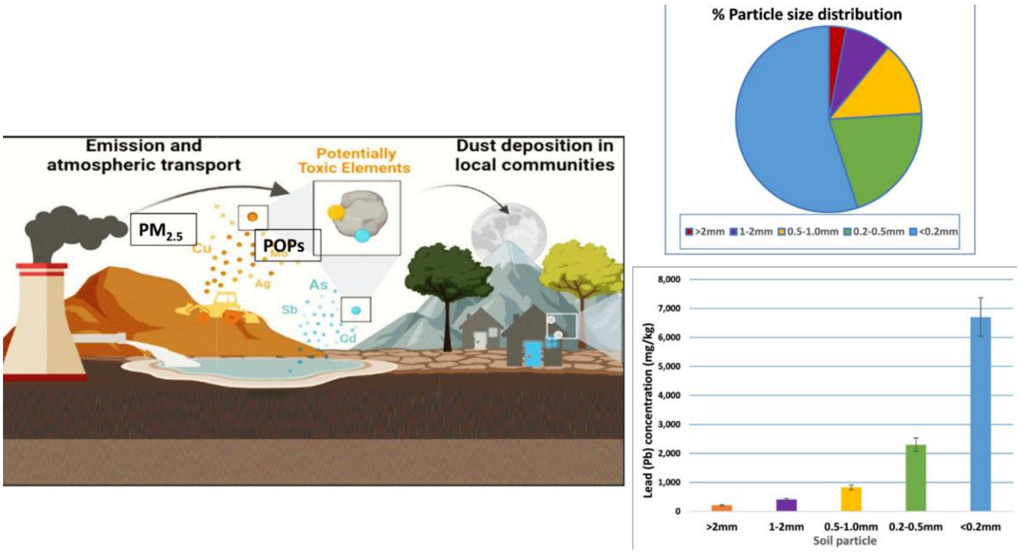

Figure 3: *Dust dispersion of contaminants. Wind erosion carries finer particles (<0.2 mm) with enriched concentration of contaminants including lead (Pb), resulting in off-site contamination*

Global climate changes, driven by both natural and anthropogenic factors, significantly impact the transportation and transformation of toxicants. Extreme weather events, such as floods induced by heavy rainfall, facilitate the movement of metals, dioxins, and hydrocarbons from contaminated to non-contaminated areas, exacerbating pollution issues (Lake et al., 2005). Additionally, wind erosion contributes to off-site heavy metal contamination, further spreading pollutants beyond their original locations (Fig. 3). In response to these challenges, enhancing remediation strategies through green technologies becomes essential, requiring precise steps for remediating contaminated lands. One effective approach is phytoremediation, which utilizes plants to absorb and detoxify contaminants. Elevated atmospheric CO_2 levels can enhance this process by improving plant growth and increasing their capacity for metal detoxification. This not only aids in remediating contaminated soils but also contributes to CO_2 fixation and emission reduction, creating a dual benefit in addressing environmental concerns.

Recognition of climate change as a global threat requires decision-making at the international level. The 2015 Paris Agreement was a milestone in the development of carbon regulation, setting priorities for reducing greenhouse gas emissions, developing technologies for their accumulation and absorption, and implementing adaptation measures. Unlike the Kyoto Protocol, the Paris Agreement transfers the initiative to the level of individual countries and regions, which creates an opportunity for a flexible approach to solving the problem. The world's leading economies have recognized the need to transition to a low-carbon development model based on the use of cleaner and more affordable energy sources.

However, many unresolved issues remain, including the speed and scale of the necessary changes, as well as their consequences for the economy and society. World leaders must not only take into account all aspects of the climate problem, but also coordinate their actions in accordance with scientific data and the international climate agenda. Including climate change issues on the agenda of global summits contributes to progress and allows for harmonizing decisions in areas such as the environment, health and the economy.

This multilateral approach provides an opportunity for a comprehensive solution to the problem of climate change, making international agreements a key tool in the fight against global warming.

The close connection between the issue of climate change and development strategies is critical, particularly regarding traditional energy, which is the primary source of greenhouse gas emissions due to fossil fuel combustion. According to the International Energy Agency (IEA), to maintain atmospheric CO_2 concentrations at a safe level (450 parts per million), countries must undergo a significant environmental and energy revolution. This transformation requires reaching the peak of hydrocarbon use no later than 2020 and transitioning towards predominantly low-emission and renewable energy sources, including natural gas, clean coal, nuclear, hydropower, wind, solar, wave, geothermal, and tidal energy.

Experts argue that a radical increase in energy efficiency is essential to achieving these revolutionary changes. By 2050, it is projected that each dollar of GDP should be produced using only half the energy that was required in 2002. The IEA estimates that by 2030, the share of renewable energy sources and nuclear energy should increase from the current 18% to 33%. Furthermore, from 2007 to 2020, carbon intensity of energy—the average CO_2 emissions per kilowatt-hour of electricity produced—should decrease by 23%, and the carbon intensity of GDP should drop by 37%. By 2020, the proportion of new cars with internal combustion engines should fall from 95% to 40%. Achieving these goals may require up to $430 billion per year in additional investments.

One of the breakthrough solutions in reducing greenhouse gas emissions from hydrocarbon energy is the development of technologies for capturing CO_2 from the atmosphere and storing it underground, known as Carbon Capture and Storage (CCS). However, the commercial implementation of such technologies is still far off, even in technologically advanced Western countries, due to their high costs.

The concept of low-emission development is central to the "New Green Deal" in the global economy, proclaimed by the UN in late 2008. This initiative aims to reorient global economic development towards a new technological base, addressing the dual challenge of reviving economic growth while combating climate change. The promotion of low-carbon energy and enhanced energy efficiency aligns well with the long-term strategic goals of leading economies worldwide—to reduce reliance on imported fossil fuels while meeting increasing energy demands. As a result, the "green" agenda has become the foundation of anti-crisis strategies in the United States, Europe, and large developing nations, gaining popularity globally. Currently, environmental investments represent a significant portion of the budget plans of countries like the USA, Germany, France, South Korea, and China, with experts estimating that approximately $436 billion has been allocated for these purposes worldwide.

The necessity of stimulating low-emission economic development strategies, especially in developing countries, was also emphasized in the "Copenhagen Accord." This highlights the growing recognition of the need for global cooperation and investment in sustainable development practices to effectively address the challenges posed by climate change.

IV. Discussion

Russia has set a goal — transition to a low-carbon development model with the prospect of achieving carbon neutrality by 2060. The consequences of climate change are included in the challenges of the Strategy for Environmental Security of the Russian Federation for the period up to 2025 (Decree of the President of the Russian Federation of 19.04.2017 No. 176), the National Plan for Adaptation of Industries and Regions to Climate Change is being implemented, the Law on Limiting Greenhouse Gas Emissions has been adopted, mandatory carbon reporting for large emitters has been introduced, and conditions have been created for initiating climate projects. Russia declares the need for the most complete consideration of the absorptive capacity of ecosystems. In the low-carbon development strategy of Russia, adopted in 2021, the main emphasis is placed on this mitigation method (mitigation measures): when implementing the target scenario, by 2050 it is expected to reduce GHG emissions by 289 million tons, and increase absorption by 665 million tons of CO_2 equivalent compared to the baseline level of 2019, that is, priority is given to absorption measures [4]. Russia's experience in developing national climate legislation and carbon regulation can become the basis for determining environmental and/or climate benchmarks for the EAEU, SCO, and BRICS. The government has adopted basic regulatory documents defining the volumes of greenhouse gas emissions reduction, the methodology for accounting for them, market, financial and legal measures stimulating low-carbon development, and much more. Russia pays great attention to taxonomy issues and is systematically working to create a Unified National System for Monitoring Climate-Active Substances [5]. The development of a national methodology will enhance the status of Russian expertise at the international level, including in negotiations on measures to adapt the economy and population to climate change.

An achievement was the signing of a protocol of intent at the SPIEF between the Federal Accreditation Service and the Global Carbon Council on the recognition of the accreditation of Russian bodies in the validation and verification of greenhouse gas emissions. This opens up new prospects for expanding cooperation with foreign countries in the field of carbon unit trading. For Russia, joint work with the Global Carbon Council is important for the development of common approaches to climate issues as part of friendly multilateral formats.

Thus, Russia today is among the countries capable of determining the vector of development of the climate agenda at the global level, forming an idea of effective ways of transition to a low-carbon economy, and also actively participating in determining the basic development strategies of the world's leading regions, based on scientific data. Russia, occupying a leading position in a number of areas of technological development, is able to offer partner countries environmental or climate benchmarks with the prospect of their subsequent possible dissemination to the EAEU, SCO, BRICS, etc.

The modern understanding of climate change is associated with a global phenomenon that has manifested itself as a result of the accumulation of greenhouse gases in the atmosphere. The peculiarity of greenhouse gases is that they are evenly distributed in the Earth's atmosphere, i.e. they do not have a local nature of influence. The problem of the greenhouse effect has not only become the subject of scientific discussions on the formation of the climate, but has also attracted wide public interest. The novelty of the climate agenda of the 21st century is associated with the identification of the limits of potential anthropogenic impact on the planet's biosphere, in contrast to the resource limitations in the understanding of R. Malthus in the 17th century [6] or in the report to the Club of Rome in 1972 "The Limits to Growth" [7].

In order to achieve the goals of reducing greenhouse gas emissions, it is important to take into account the positions of different countries and adhere to the principle of common but differentiated responsibility. Climate negotiations, as a rule, take into account the position of the participants in relation to both actions to mitigate the effects of global warming by reducing the anthropogenic impact on the environment by reducing or limiting greenhouse gas emissions, and actions to adapt to the effects of climate change. In the first case, the basis is collective agreements at the level of entities, such as countries or subnational associations, on joint principles and approaches to solving priority problems in the field of climate. The Paris Agreement (2015) points to the importance of adaptation measures, including ensuring direct financing of adaptation activities. In the second case, we are talking about the development of specific actions and events at the level of specific stakeholder groups (regions, enterprises, population and others) to increase their ability to cope with such consequences, reduce their vulnerability to climate risks. In this regard, it is extremely important to show the equal importance of mitigation and adaptation issues.

According to UN forecasts, the main population growth, and therefore sales markets, occurs in developing countries, so the main resources will be “attracted” by these regions. Developing countries in most cases follow the development trajectory of more developed countries (urbanization, industrialization, priority development of personal transport in relation to public transport, etc.).

The expected growth in energy and other resource consumption in developing countries has increased the concerns of developed countries and prompted them to form protective mechanisms, declare the need to restructure the energy system and reduce anthropogenic emissions by abandoning the consumption of fossil fuels. Developed countries have formed a coalition to form a global system of restrictive mechanisms for the use of hydrocarbons, including directive support for renewable technologies, based on a solid ideological foundation and the popularization of climate ideas to form a loyal public opinion. At the level of the OECD (2009) and ASEAN (2010), competing concepts of a "green economy" and "green growth" were presented. The demand for "green" policy in developed countries during this period is largely due to the lack of alternative concepts of economic growth and the conviction of political elites in the correct choice of a method for a rapid transition to a new technological order in order to maintain leading positions in the world economy. More and more economists, based on empirical data on resource use and greenhouse gas emissions, reject the concept of green growth, concluding that green growth is likely to be a mistaken goal and that alternative development strategies should be sought [8]. In addition, accounting for greenhouse gas emissions and absorption in the world does not fully reflect the objective picture; the methods used need to be improved, given that climate data are increasingly used for international comparisons, including as a factor in the competitiveness of producers from different countries [9].

Thus, at the present stage, the climate discourse projects the influence of two basic ideas — ensuring energy security and searching for a new model of intensive development. The EAEU, BRICS and SCO, uniting countries with rapidly developing economies, act as a counterweight to coalitions of developed countries. The potential for pooling resources and cooperation between participating countries.

Abstract

One of the main directions of environmental protection and pollution prevention is the improvement of technological processes. The drilling of deep oil and gas wells is a very complex technological process, the violation of which can lead to various emergencies that pollute the environment. Therefore, well rehabilitation is becoming an increasingly important aspect of ensuring the sustainability and efficiency of the production process. This paper analyses the performance of equipment used in oil well rehabilitation. For this purpose, a classification of accidents in production and drilling wells is presented and a qualitative evaluation of the main oil well rehabilitation methods and the equipment used in this process (milling, capture, flushing tools and raisers) is carried out in order to determine their advantages and disadvantages.

Keywords: acid mudding, hydraulic fracturing, milling tools, trapping tools, plugging tools, reiber

I. Introduction

One of the reasons that reduce the efficiency of drilling and well operations is accidents. In oil and gas wells, an accident is an interruption of technological processes caused by the seizure or breakage of downhole tools and equipment, as well as the fall of individual parts and components downhole. Modern drilling is characterised by continuous increase of well depths, reduction of well diameter in the lower intervals, increase of complications. As a result, the likelihood of accidents in the operation of the above-mentioned wells (both producing and drilling wells) increases.

An important measure to reduce the accident rate is the prevention of accidents and complications, as well as systematic preventive maintenance. In order to inform the strategy of these measures, it is necessary to study the experience of accidents in the production and drilling of wells. This should be done by analysing accidents in wells:

- the location and depth of the emergency object in the well;
- the shape, size and diameter of the emergency object;
- the condition of the borehole walls,
- the physical and mechanical properties of the material of the emergency object and the degree of its adhesion;
- the degree of risk of gas and oil spillage, etc.

All of this is a sine qua non for the improvement of existing methods and the development of new methods and technical means to speed up the commissioning of idle wells at minimum cost. For this purpose, it is necessary to establish a classification of accidents in production and drilling wells, which is presented below:

1. downhole pipe accidents
2. accidents involving downhole motors, instruments (devices), packers and drill string threads;
3. accidents associated with geophysical surveys;
4. accidents involving rock destruction tools;
4. accidents involving cables, ropes, wires;
5. accidents related to foreign objects falling into the well;
6. fire and explosion accidents;
7. other.

However, the classification which groups objects into classes mainly on the basis of the type of emergency object is conditional and only acceptable for simple accidents, i.e. cases where there is a single type of emergency object in the well. For combined accidents, i.e. when a combination of accident objects is present in the well, this classification loses all meaning. Therefore, the classification should be based on a formal basis. Nevertheless, the proposed simple accident classification [1] is a guideline for the development, maintenance and improvement of the reliability, operational characteristics of downhole tools to prevent accidents. According to this classification, the data on the oil industry of the Commonwealth countries on the distribution of accidents, the corresponding volume of repairs and tripping operations are given in the form of a diagram in Fig. 1.

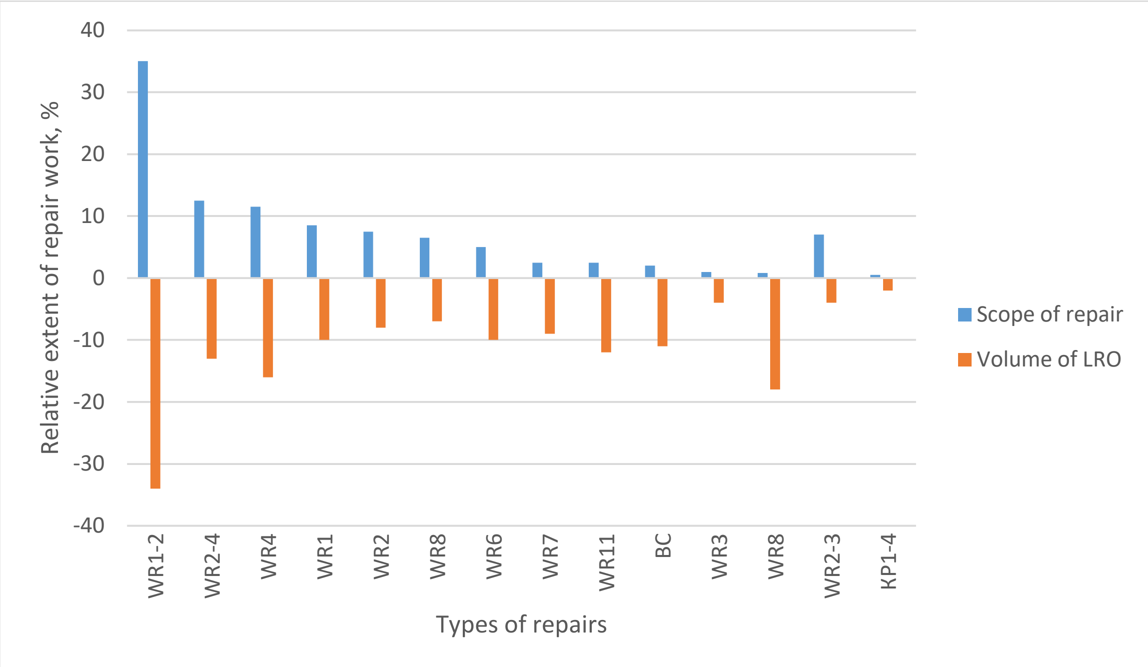

Figure 1: *Diagram of repair volumes and corresponding of repairs and corresponding launch and recovery operations (LRO):*

WR1-2 - separation of separate formations; WR2-4 - elimination of leakage by partial replacement of the production string; WR4 - transition to other horizons and connection of formations; WR1 - repair and insulation works; WR2 - elimination of leakage of the production string; WR8 - well exploration; WR6 - Complex of underground works for restoration of well performance using technical elements of drilling, including cabling of horizontal sections of the well; WR7 - Treatment of the formation zone at the bottom of the well and induction of flow; WR11 - preservation and re-conservation of the well; WR13 - other types of works; WR2-3 - elimination of leakages by running additional casing of smaller diameter; WR1-4 - cement ring construction behind production, intermediate casing, conductor.

In addition, oil wells are subject to a number of unfavourable factors such as clogging, corrosion and fouling. These problems can significantly reduce well performance. To overcome these problems, specialised equipment is used to restore well performance.

II. Methods

The following are the main methods of restoring the operability of oil wells and the equipment used.

I. Well flushing method.

Flushing an oil well involves:

- Transfer of hydraulic energy from pump to turbo or electric drill, bit, downhole motor;

- Cooling, lubrication and corrosion protection of the bit as the mud passes through the wellbore. Oxidative destruction of metal parts of the equipment occurs due to the action of oxygen dissolved in the mud, hydrogen sulphide and rock salts. Anticorrosive properties are imparted to the working drilling fluid by the addition of inhibitors:

- flushing of oil wells during drilling allows the reduction of abrasive wear during drilling by timely and proper cleaning of drilling fluid from solid particles of cuttings;

- facilitating the drilling process through the kinetic energy of the fluid as it leaves the drill bit and reducing the coefficient of friction. This is particularly effective when working in loose soils;

- pressurising the borehole to prevent gas and oil spillage and collapse of the borehole walls when working in unstable rock;

- temporarily maintaining the suspended state of the mud particles during pump shutdown (in an emergency situation). For this purpose, the drilling mud is given thixotropic properties by additives that allow it to transform from ash to gel;

- prevention of technological difficulties in the drilling process, including differential seizure of the drill string;

- strengthening the wellbore channel when working in weak and fractured rock by creating a reinforced clay crust;

- preserving reservoir productivity in the downhole zone.

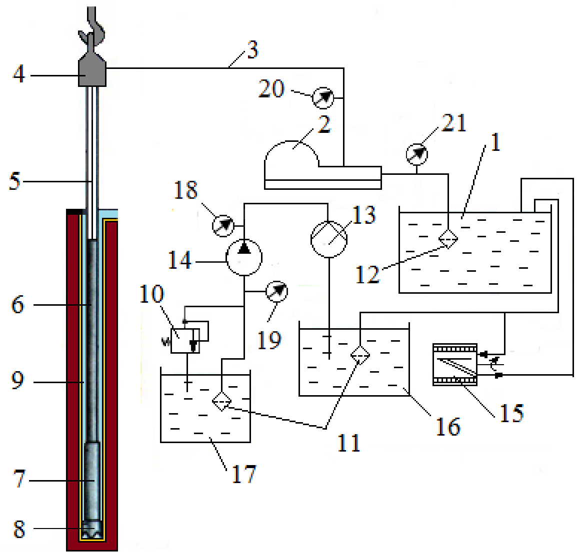

Figure 2: *Direct well flushing scheme:*
1 - mud tank; 2 - pump; 3 - flexible hose; 4 - swivel; 5 - drive pipe; 6 - drill string; 7 - hydraulic motor; 8 - drill bit; 9 - annular duct; 10 - safety valve; 11, 12 - filters; 13 - hydrocyclone; 14 - auxiliary pump; 15 - centrifuge; 16, 17 - sumps; 18-21 - pressure gauges.

The disadvantage is that sand plugs form during the drilling process as a result of the thermal effect on the reservoirs. As a result, additional time is spent flushing the well to "clean water" before reaming the casing. It is also important to note that the direct circulation method requires a large amount of working fluid, especially when drilling with a maximum diameter bit.

2. Acid dissolution - used to remove sediments and increase formation permeability. Analyses include evaluation of the concentration of acids used, depth of penetration and changes in well productivity.

Acid dissolution plays an important role in the oil and gas industry and is used to remove deposits and clean up wells. Specialist equipment is required to carry out this process effectively. Below is a list of equipment that can be used for acid dissolution in the oil and gas industry:

1. Acid pumps - must be corrosion resistant and capable of handling corrosive media.
2. Acid supply tanks - these are acid tanks and reservoirs for the storage and supply of acid solutions and metering systems for accurate and uniform acid distribution (Table 1).
3. Instrumentation - this includes instrumentation to monitor pH, temperature and acid concentration, as well as pressure and flow monitoring equipment: to ensure process safety and efficiency.
4. Acid resistant tubing and casing to ensure well longevity and safety.
5. Waste treatment equipment as part of the decontamination system to neutralise spent acid solutions.
6. Corrosion monitoring equipment to assess the effects of acid on equipment.

Table 1: *Volume of acid injected (m^3) per 1 m of uncovered formation thickness*

Number of treatments	Type of collector	
	Low permeable	Highly permeable
1	0,4 ÷ 0,6	0,7 ÷ 1,1
2 or more	0,6 ÷ 1,7	1,1-1,6

It is important to comply with safety and environmental standards when using acids in the oil and gas industry. Exact equipment requirements may vary depending on the specific process and field characteristics.

3. Hydraulic fracturing - used to increase permeability and improve production. This technique creates fractures in the rock to allow increased fluid (oil and gas) flow to the wellbore. When using this technique, it is necessary to determine the effect of pressure and volume of water used on the change in well production rate.

Here are some basic aspects of this technique:

- Fluid preparation. A special fluid known as "hydraulic fluid" is prepared at the surface. This fluid usually consists of water, additives to improve properties and, importantly, proppants (small particles that help prevent cracks from closing after flushing).
- Fluid injection. A hydraulic fluid under pressure is injected into the well. This creates fractures in the rock and increases the permeability of the formation.
- Proppant into the fractures. When fractures are created, proppant (particles such as sand or ceramics) is injected into the fractures to prevent them from closing after the fracturing process is complete.

The equipment used in hydraulic fracturing includes

- Hydraulic pumps to generate sufficient water pressure to overcome rock resistance.
- Special pumps to inject proppant into the fractures.
- Monitoring equipment, i.e. various tools such as seismic and sonic monitoring systems are used to control and optimise the process.

Drawbacks. Hydraulic fracturing is a complex and controversial technology, and its use requires a balanced approach that considers both economic benefits and environmental risks. There are concerns about potential negative environmental impacts such as groundwater contamination, seismic activity and others. Different countries and regions have different laws and regulations governing the use of fracking technology. The technology is a matter of public concern because of the environmental risks associated with it. Potential negative impacts must be considered when implementing this technology.

Depending on the type and degree of complexity of the accident, well repair and recovery operations are carried out mainly by destroying emergency equipment and by containment operations, which also include tackling operations.

The most common destruction methods are chemical, mechanical and thermal destruction of emergency objects in the well. The analysis of these methods shows the efficiency of the mechanical destruction method as the most economical and easy to use. Various types of milling cutters are widely used for this purpose.

At present, some experience has been gained in various oil regions of the country with the use of downhole cutters with a cutting part in the form of a reinforcement made of composite material [5.59]. However, the capacities of the country's machine-building industry are not sufficient. to meet the oil industry's ever-increasing demand for these tools. The situation is further aggravated by the low performance indicators of the tools produced by the machine-building industry of the CIS countries. This indicates that the process of interaction between the tools and the object to be destroyed is insufficiently studied, despite the fact that the milling process is similar to the well-studied processes of rock destruction by chisels and metal processing by cutting [7, 4].

Reserves for improving and increasing the efficiency of the milling process should be sought in the following directions

1. Research of composite materials, which are coated on the body of tools and form their cutting part;

2. Reliable theoretical and experimental modelling of the process of their interaction with the emergency object;

3. Synthesis of wear-resistant materials as armament with given properties, compatible constructive and technological parameters of their functioning; in borehole conditions.

A number of works [2] are devoted to the study of various aspects of the production and operation of composite materials and the serviceability of composite products.

A significant increase in the cutting properties and wear resistance of tools can be achieved by proper orientation of shape-classified grains of solid filler material [6].

Ensuring and improving the cutting properties of milling tools in general is a complex set of different problems involving the implementation of a number of design, technological and operational measures [5]. The milling tools shown in (Fig.3) are the result of attempts to solve the problem of intensification of the milling process by appropriate design changes. The operational measures should include the prevention of thermal shock in the heating-cooling cycle (Fig.4) and thermal fatigue on the cutting surface of the tool, scattering [8] the values of mode-technological factors.

The kinetics of the wear processes of working bodies of tools such as downhole milling cutters and its interrelationship with the thermophysical processes accompanying tool operation are very complex and multifactorial. The study of this relationship in the thermal formulation is to solve contact thermodynamic problems with the phenomenon of wear. The solution of such a problem is ultimately reduced to the differentiation of complex integral equations with moving natural boundary conditions. Obviously, the complexity of both the formulation and the solution explains the absence of such studies. The authors [9] have attempted to solve such a problem in an experimental formulation, and their work differs favourably from previous studies in this direction.

It was found that, depending on the energy supplied to the bottom hole, pre-critical (moderate wear) and sub-critical (catastrophic wear) modes of tool wear are possible. The transition from one wear mode to the other is explained by the change in cooling conditions; at the transition there is a temperature jump (Fig.4) at the tool face, which in turn contributes to the change in the character of the wear process. Simultaneously with a sharp increase in temperature, there is a jump in power consumption (N ~ Fu, where N - power consumption, F - axial load, u - tool speed) at the transition to subcritical operation. Processing of the experimental results showed that in the subcritical mode the wear of the matrix of the cutting part of the tool increases 3-4 times. As a result, it was concluded that it is possible to solve the problem of automatic maintenance of the operating mode in the subcritical range without burns and catastrophic wear.

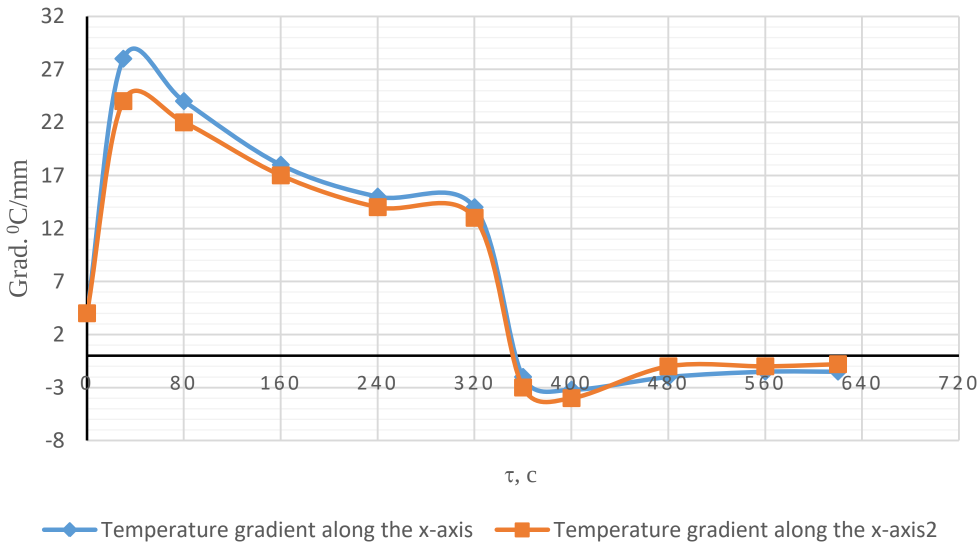

Figure 4: *Variation of temperature gradients in the heating/cooling cycle*

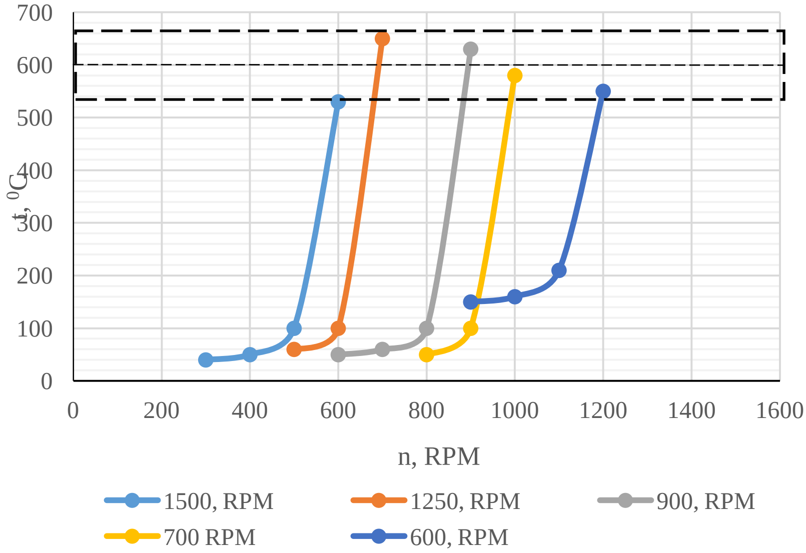
The disadvantage of this work is that the investigated factors do not include the flow rate of the flushing fluid, the flushing scheme and a number of other factors that significantly influence the intensity of the thermophysical process that develops during the destruction of an emergency object. However, the rheology of the flushing fluid, its composition and flow regime is one of the most accessible, universal and, in most cases, economical means of increasing the thermomechanical stability and wear resistance of cutting tools [3-5].

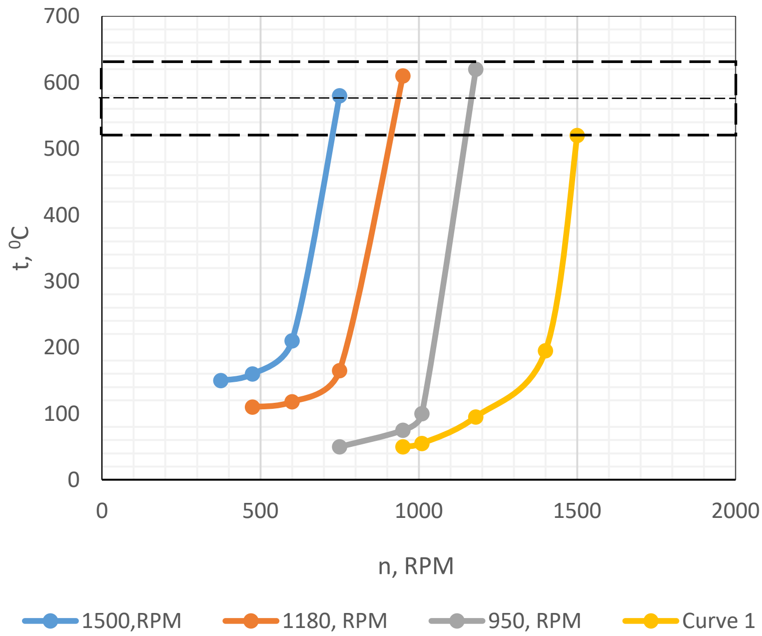
One of the most complex and labour-intensive types of work performed during overhaul is catching work [8,9]. The tools used for catching work are divided into three groups according to the principle of pipe gripping (Fiq.5):

- Tools with pay and wedge gripping devices;

- Tools with thread-cutting gripping devices;
- Other gripping tools.



a



b

Figure 5: *Bit temperature as a function of axial load (a) and drill speed (b)*

The efficiency of slotted tools, which are the most widely used in practice, is determined by the perfection of the design and kinematic characteristics of the gripping device, which determine the reliability of the adhesion of the slots to the surface of the pipe body for successful unscrewing. The main load-bearing node of the jaws is also the node of the gripping device, the reliability of which determines the operability of the tool design as a whole.

It should be noted that a number of theoretical and experimental works [3-7] are devoted to the study of the force and kinematic interaction of the gripping device with the surface of the pipe to be gripped. Due to a significant simplification of the force and geometrical relations of the interaction process, these works do not fully reflect the actual deformed state of the gripper elements and the surface of the catching pipe.

The main factors that determine the design characteristics of the gripper are the reduction of the specific pressure generated by the movement of the dies on the inclined support surface and the prevention of changes in the shape of the catching tube in the gripping zone. In addition, the requirements of the specified tool should be met without compromising the tool's load-bearing capacity.

One of such technical solutions in the specified direction is a downhole tool with a gripping device in the form of a spiral, developed in SOCAR. Such a design of the gripping device with optimum design parameters allows to increase the working area of contact with the pipe and thus to make full use of the rated load capacity of catching tools when eliminating complex accidents by applying maximum axial loads (Fig.6).

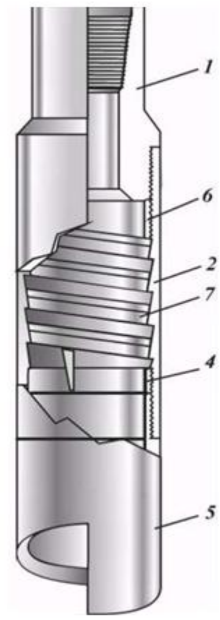


Figure 6: *Catch tool with spiral gripping device:*
1 – upper guide; 2 – housing; 3 – plate grid; 4 – limiting ring;
5 – guiding funnel; 6 – paker; 7 – spiral grid

The problem of increasing the load capacity of catchers with payload gripping devices should be solved by perfecting the process of interaction with the object to be caught. This interaction should not reduce the load-bearing capacity of the caught object in the gripping zone. As a result, the possibilities for increasing the load capacity of flame arresters, which is particularly important for preventing accidents in deep wells, are limited. Therefore, in order to increase the efficiency of catching operations in deep wells together with mechanical flame gripping devices, it is necessary to develop designs of catchers whose gripping devices do not deform their surface when interacting with the trapped pipe.

According to the existing classification of accidents [4], unlike the first (accidents with downhole pipes) and second (accidents with downhole motors, tools, packers and drill string bottoms) groups of accidents, other types of accidents are possible (third group - accidents with cables, ropes, wires, fourth group - other accidents), for the elimination of which downhole cleaning tools are used [6, 8].

This class of equipment includes tools that use the effect of physical fields (magnetic catchers, magnetic milling machines, etc.) to clean the borehole from small metal objects. Despite the fact that the performance of these tools has been studied by a number of authors [4, 5], the efficiency of their use in field practice is comparatively low.

In [5] the reasons for the unsatisfactory operation of magnetic cutters in connection with the increase of the borehole depth are considered, among which a special place is given to the breakaway force arising in the process of technological operation at the cleaning of the borehole from small metal objects.

In order to improve the efficiency of operation, it is considered necessary to make changes in the design of magnetic milling machines produced by the industry of the CIS countries. For this purpose, it is necessary, first of all, to study various factors that determine the design of magnetic milling machines and predetermine the efficiency of their application in deep boreholes. This problem is addressed in the paper [4.49], in which the results of studies on the dependence of the magnetic cutter attraction force on metal objects at different distances from the pole, the influence of the type of washing liquids and temperature on the tool traction characteristics are given.

It is expedient to continue research in this direction in order to meet the requirements of the practice of cleaning the borehole from metal objects.

Accident-free drilling is the main direction of the solution to the problem of improving the quality of drilling and is determined both by the perfection of accident prevention methods and by the adaptation of the measures adopted for this purpose to specific conditions. Among the accidents, the most common in practice (especially in deep wells) and requiring the application of very labour-intensive measures is the seizure of downhole equipment. Because of the time-consuming nature of stuck wells, the means and methods of both preventing and remedying this class of phenomena are constantly being improved [4]. A wide variety of methods are currently used to clear stuck wells. Depending on the situation in the well when a stuck well occurs, any one of these methods, or a particular sequential set of them, may be effective. This is usually the case when the choice of action or set of actions is appropriate to the conditions under which the seizure occurs and the nature of the process. As a rule, the technology of eliminating the seizure is based on the sequential application of means and methods, as well as on their alternation (especially in complex geological and technical conditions). In this case, in order to reduce both material and time costs, it is necessary to have a (theoretical) tool for choosing a rational strategy of tackling.

The use of special technical means (percussors, yasses, vibrators, etc.), the classification of which is given in Fig.7, is no less widespread among the methods of tackling liquidation. These technical means are mainly divided into surface and submersible ones. Surface equipment is not widely used because the depth at which it is effective does not exceed 200 metres. Submersible devices, both mechanical and hydraulic, are mainly used in deep drilling. The main requirements for submersible impact devices to ensure their effectiveness in tackling are

- simplicity of design;
- simple and accident-free application technology;
- the ability to apply shock impulses in the immediate vicinity of the tacking zone.
- possibility to regulate the impact force at the wellhead;
- possibility to apply repeated directional blows the required number of times both from top to bottom and from bottom to top to unseat the seized pipe string;
- reusability, etc.

At present both in domestic [7] and foreign field practice [3, 5] of liquidation of seizure phenomena various shock devices are used, satisfying to some extent the above-mentioned requirements. The main design characteristic of these devices is the dynamic load imparted to the seized part of the string. The application of dynamic load to the pipe string during attempts to release it contributes to the occurrence of significant stresses in it, which may lead to failure. Therefore, the study of the stress state of a tacked pipe string is of great practical interest [4, 6, 7].

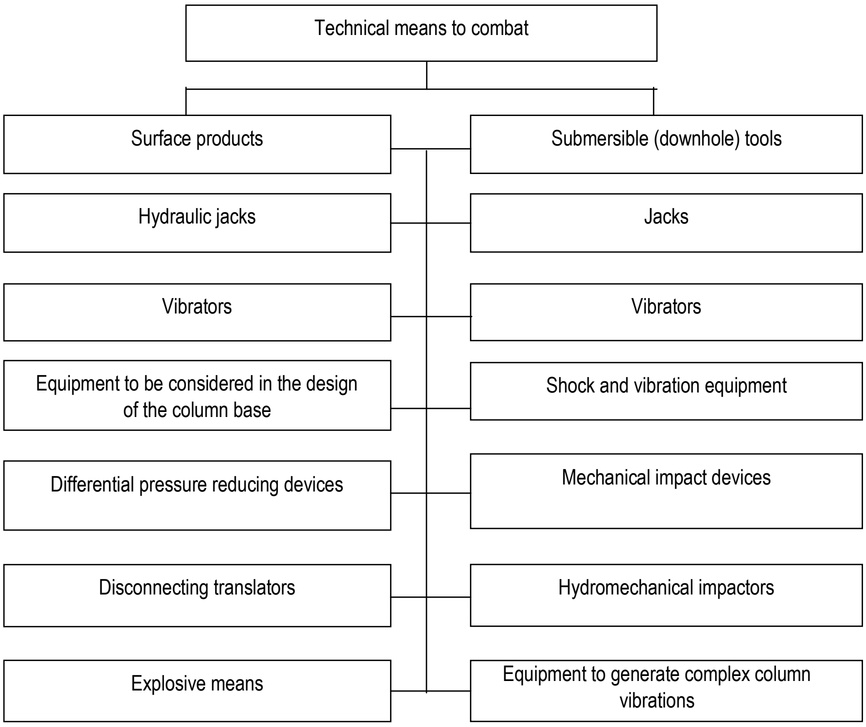

Figure 7: *Classification of technical means of removing tackle*

As a result of a certain class of theoretical and practical calculations, the authors [1-3] found that the dynamic coefficient decreases significantly with increasing well depth. This is explained by the fact that the static component of the total load absorbed by the string increases with increasing well depth. Furthermore, the determining parameters of the dynamic component are the speed of the drill string movement and the number of blows applied to the stuck part of the string. The disadvantage of this work is that it investigates the wave process induced by the application of impulse loads to the stuck part of the string in one direction (from top to bottom) and does not determine the number of blows required to complete the release without damage. However, the conclusions drawn from the results of the work, which consist in the need to impart a large variation in the amount of movement to the gripped part of the string in each test, within the limits allowed by the strength of the pipe, are very valuable and can be a starting point for the development of effective impact devices.

Wave processes in longitudinal elastoplastic impacts are also studied in [1-5]. The efficiency of impact devices used for tacking is also assessed by the possibility of disengagement of the tacked pipe string by impact in opposite directions. Therefore, modelling the tacking process by wave processes developed in one direction does not correspond to the physical model of the interaction between the impactor and the tacked part of the pipe string. This circumstance does not allow to use the models proposed by the above mentioned works to describe the dynamics of the interaction between the impactor and the seized part of the string. In order to accurately reproduce this interaction, it is necessary to develop and study its mathematical model, which provides for the excitation of wave processes developed in opposite directions.

Wells that are technically impossible or economically unviable to rehabilitate using the above methods are rehabilitated by sidetracking and drilling a second well. The rehabilitation of shut-in wells by sidetracking and drilling a second well is an important part of the package of measures aimed at stabilizing the level of oil production in long-developed areas. This method allows wells to be reworked in areas where the conditions and state of reservoir development make it difficult and unprofitable to drill new wells. Sidetracking and drilling a second well increases the number of producing wells at the expense of inactive and previously abandoned wells. This also allows the disturbed development network to be reestablished, corrections to be made to the previous development to be made and previously missed oil targets to be identified, ultimately increasing the oil recovery factor of old reservoirs. The issue of maximizing oil recovery in the late stages of field development has recently become of great national economic importance.

Since the development and introduction of the method of sidetracking and drilling of the second well into the practice of rehabilitation works, both the technology of the works and the technical means for their implementation have been significantly improved. This contributed to the wide application of the method in the oil fields of the North Caucasus and Azerbaijan and some other areas of the CIS countries [1-5], as well as abroad [6]. Recently, however, the volume of well rehabilitation using this method has decreased significantly due to the increase in well depths and the complexity of the operations. The complexity of the sidetracking process in deep wells places special demands on the development of technical means and technological measures for this purpose. It should be noted that the efficiency of sidetracking, in addition to the use of high-performance equipment and technology, is also significantly influenced by the correct choice of the object to be targeted [5.7]. This means that it is first necessary to assess the economic feasibility of this operation in accordance with the geological and technical characteristics of the wells. In studying this issue, criteria should be established for assessing the technical and economic feasibility in each individual case of workover or reworking of a well.

The problem of choosing the shape of the deflection surface of the deflection wedge is very controversial, and it should be solved not independently for the deflection wedge, but in the complex of problems related to obtaining a "window" of the required dimensions in the production line from the point of view of tool permeability. This means that, in order to obtain a "window" of the required dimensions with good permeability, it is necessary to develop compatible conditions "well design - deflector - ripple - technological factors". In [3], "tentative" attempts were made to develop these conditions, which would allow the shape and size of the deflector surface to be designed according to the "window" permeability criterion. According to the results of experimental studies with the design of the developed rayber, it was found that the most acceptable is the flat shape of the deflection surface, and the design of such a deflector was developed [4]. However, when flat wedges are used, the specific pressure generated during the operation of the rayber is greater on the wedge surface than on the pipe surface [8]. As a result, a strip of metal is cut from the wedge body rather than from the pipe wall, as was the case with the "window" cuts in the production string at Khydyzhenneft Oil and Gas Production Department.

After the deflector has been lowered and landed, a window is cut in the production string. Opening the "window" in the string is a very important operation. The degree of perfection of the working technology and structures, the equipment used for this purpose determine the configuration and dimensions of the "window" to be cut in the column. Conformity of the configuration and dimensions of the "window" to the further conditions of the second borehole conduction is estimated by the character of possibility of drilling tools and geophysical instruments used for various purposes during drilling.

Otherwise, as practice shows, the results of works are reduced to obtaining a "window" with wrong dimensions, which considerably complicates further work, obtaining a "window" with wrong dimensions can be promoted by such constructive features of cutting tools and deflectors.

In spite of the significant improvement of the second hole cutting process in recent years, it is not always possible to avoid additional time and costs due to possible complications [1-3].

The most common accidents and complications are 1) jamming of the cutting tool; 2) premature exit of the cutting tool behind the string; 3) breakage of drill pipes or breakage of the threaded connection; 4) displacement from the landing place or rotation of the deflector around the axis; 5) strong absorption of the mud.

In some cases, in order to obtain a high mechanical speed, the established rules for the technology of opening the "window" in the string are not respected. The mechanical opening speed depends on the load axis, the number of rotor revolutions, the steel grade and the condition of the production column, the pump capacity and the design features of the tool and the deflector. When designing the conditions for cutting a "window" in the string, it is necessary to provide such a combination of the above factors that would allow obtaining a "window" of the required configuration and dimensions and satisfy the criterion of absence of complications such as "tool jamming". In addition to the jamming of the tool with a full stop, there is often an instantaneous jamming and release of the tool. In this case, the tool works by jolts, as a result of which there is a phenomenon of torque impact, accompanied by the emergence in the drill pipes, reaching quite high values of stresses that can lead to the breakage of drill pipes [3].

Summarising the above phenomena, it can be concluded that the cause of complications and accidents when opening a "window" in the production string are design deficiencies of cutting tools and deflectors, their incompatibility with each other and with the well conditions, the lack of a reasonable process technology and of appropriate criteria for assessing the quality of the cut "window". A vector combining the design parameters of the borehole, cutting tool and deflector, as well as the technological parameters of window cutting, can serve as a state vector for the development of such criteria. Depending on the degree of compatibility of these parameters, the cut "window" can be of three classes: 1) "window" good - passable; 2) "window" satisfactory - passable, but with a risk of jamming; 3) "window" unsatisfactory - not passable for the cutting tool. Naturally, this poses the task of developing the necessary algorithm, in the state vector space for the possibility of designing the conditions of cutting through the "window" of good quality.

The main drawback of previous work in this area is that it has focused on the study of local problems in isolation, which has not allowed us to develop a set of measures to improve the quality of the "window". In particular, the design of the deflector [5] and the window cutting device [9] have been improved in order to obtain a full profile window equal to the line of the deflector chamfer and to prevent premature tool exit behind the column. The design of the deflector (although the degree of its manufacturability is relatively low) and the design of the device are both highly original.

However, the unconditional efficiency of their use together (or in combination with other designs) cannot be claimed. In order to assess the effectiveness of the interaction between the deflector and the cutting tool, [7.3] presents the results of experimental studies of five variants of their combinations. The aim of the experiments was to study the influence of the design of the applied technique on the length and shape of the "window" and to develop measures for selecting the most effective design of the cutting tool and deflector, as well as to determine the optimum mode of opening the "window".

Due to the fact that the designs and shapes of the cutting tools (Fig.8) and deflectors used are different, it is of great practical importance to determine the value of the areas where friction occurs. The area of friction where both the string and the deflector of cutting tools of different design rub against the wall of the production string in the process of opening the "window" determines "the value of the specific pressure at the points of contact between the interacting bodies.

Perfect are the designs of cutting tools that do not wipe the deflector, cut through the column to the end of the deflector bevel and create a high specific pressure on the friction surface at a relatively low load. The magnitude of this pressure is determined both by the geometric shape of the cutting part of the tool and the direction of the main vector of the forces acting on it as it cuts through the "window".

In order to ensure trouble-free operation of the drill string and avoid premature cutting tool exit, the authors [9] developed and tested a Drill Pipe Bending Straightener (DPBS) on a number of SOCAR wells. The use of the Drill Pipe Bending Rectifier (DPBR) when opening the "window" in cased wells prevents the premature exit of the cutting tool from the string, regardless of the axial loads, and makes it possible to reduce the resulting bending stresses in the drill pipe by about 10 times. It is recommended that the first drill pipe bending straightener be installed at a distance of (1.5-3) m from the cutting tool, and subsequent ones at a distance of 6 m from each other. However, these recommendations are not confirmed theoretically, which does not allow to adapt the arrangement of drill pipe straighteners to specific conditions of their operation in the process of opening the "window" in the production string.

III. Results

The result of the analysis of the serviceability of tools used for carrying out repair and recovery operations in oil and gas wells will allow to determine the main directions of improvement of repair techniques and technology. Formation of a set of tasks to solve the problem of improving the efficiency of production of repair and recovery operations at emergency oil and gas wells.

Analysis of the performance of oil well rehabilitation equipment is a key element in improving the efficiency of production and ensuring stable operation of oil companies. The analysis includes the change in daily and annual production after the introduction of new equipment. It should be noted that efficient equipment also reduces well maintenance and workover costs.

The introduction of new technologies and the continuous improvement of equipment play a crucial role in achieving this goal. In the future, we can expect to see further development and innovation in well rehabilitation technology, leading to more efficient and sustainable oil production.

Abstract

This paper explores the intricate relationship between human health, ecological status, and quality of life, emphasizing the significance of ecosystem health as a determinant of overall well-being. The degradation of ecosystems due to human activities poses a substantial threat to public health, affecting not only physical well-being but also mental health and social cohesion. We analyze various ecological factors, including air and water quality, biodiversity, and green spaces, which directly influence health outcomes and quality of life. By synthesizing existing literature and empirical data, this study underscores the importance of sustainable environmental practices and policies in promoting human health. The findings highlight the need for integrated approaches that encompass ecological conservation, public health initiatives, and community engagement to foster a healthier population and environment. Ultimately, this paper advocates for a holistic understanding of the interconnectedness of human health and ecosystem vitality, calling for collaborative efforts among stakeholders to enhance both ecological and human well-being.

Keywords: human health, ecosystem health, quality of life, environmental sustainability, public health, biodiversity, air quality, water quality, green spaces, social cohesion.

I. Introduction

The relationship between human health and ecological status has garnered increasing attention in recent years, driven by a growing awareness of how environmental factors significantly influence overall well-being. As populations expand and industrialization intensifies, the degradation of natural ecosystems has escalated, leading to adverse health outcomes. The degradation of the environment—manifested through pollution, loss of biodiversity, and climate change—poses considerable risks not only to physical health but also to mental well-being and social cohesion.

Ecosystems provide vital services that directly support human health, including clean air, safe drinking water, nutritious food, and spaces for recreation and mental relaxation. The Millennium Ecosystem Assessment (2005) underscored the importance of these ecosystem services in sustaining human life, highlighting that the health of ecosystems directly correlates with the quality of life experienced by communities. For instance, polluted air and water sources have been linked to a range of health issues, including respiratory diseases, cardiovascular conditions, and even mental health disorders. Furthermore, the loss of biodiversity can disrupt the balance of natural systems, reducing their resilience and ability to adapt to changing conditions, which can further exacerbate health risks.

Despite this clear interconnection, traditional public health approaches often fail to incorporate ecological perspectives, resulting in fragmented strategies that overlook the broader environmental determinants of health. As such, there is a pressing need for integrated approaches that recognize the intricate links between ecological integrity and human health. This includes not only the need to address immediate health concerns but also to engage in proactive ecological conservation efforts that safeguard the health of ecosystems and, by extension, the populations that depend on them.

In this paper, we will explore the multidimensional relationship between human health, ecological status, and quality of life. We will examine key factors influencing this relationship, including air and water quality, biodiversity, and the availability of green spaces, while emphasizing the implications for public health policies and practices. By synthesizing existing literature and empirical research, we aim to highlight the critical need for collaborative efforts among various stakeholders, including policymakers, public health officials, and environmental organizations, to foster a healthier population and environment. Ultimately, this work advocates for a holistic understanding of the interconnectedness of human health and ecosystem vitality, emphasizing the importance of sustainable practices and community engagement in enhancing both ecological and human well-being.

II. Methods

To explore the relationship between human health and ecological status, this study employs three primary research methods: literature review, empirical analysis, and case studies. Each method offers unique insights into how ecological factors influence health outcomes and quality of life.

1. Literature Review

The literature review involves a comprehensive analysis of existing research related to human health and ecosystem interactions. This method encompasses studies published in peer-reviewed journals, reports from international organizations (such as the World Health Organization and the United Nations), and relevant grey literature. The review will focus on identifying key themes, such as the impact of air and water quality on health, the role of green spaces in promoting mental well-being, and the effects of biodiversity loss on disease prevalence. By synthesizing findings from multiple sources, the literature review aims to provide a holistic understanding of the current state of knowledge on the subject, highlight gaps in the literature, and inform future research directions.

2. Empirical Analysis

Empirical analysis will involve the collection and statistical examination of quantitative data to assess the relationships between ecological indicators and health outcomes. This method will utilize existing datasets from national health surveys, environmental monitoring agencies, and public health databases. Key ecological indicators may include air and water quality measurements, biodiversity indices, and green space availability. Health outcomes of interest could encompass rates of respiratory diseases, cardiovascular conditions, and mental health disorders. By employing statistical techniques such as regression analysis and correlation studies, this method will aim to quantify the strength and significance of associations between ecological factors and health outcomes, offering empirical evidence to support the hypotheses derived from the literature review.

3. Case Studies

The case study method involves an in-depth examination of specific geographic locations or communities to illustrate the practical implications of the relationship between human health and ecological status. Selected case studies may focus on areas experiencing notable environmental challenges, such as urban pollution hotspots, regions facing water scarcity, or communities with rich biodiversity that have seen health benefits. Through qualitative data collection methods, including interviews, surveys, and participant observations, this approach will provide insights into local experiences, perceptions, and behaviors related to health and the environment. Case studies will also allow for the exploration of community-level interventions and policies that have successfully linked ecological preservation with improved health outcomes, thereby offering valuable lessons for broader application.

By employing these three methods—literature review, empirical analysis, and case studies—this study aims to provide a comprehensive understanding of the complex interplay between human health, ecological status, and quality of life. This multifaceted approach ensures that both theoretical insights and practical applications are considered, ultimately informing public health strategies and environmental policies.

III. Results

Human health plays a crucial role in the overall well-being of populations and is closely linked to the state and functionality of ecosystems, particularly their capacity to deliver healthy and adequate ecosystem services, as emphasized by the Millennium Ecosystem Assessment (MEA). This paper aims to review existing literature that explores the connections between ecosystem services and human well-being, beginning with a reinterpretation of the MEA framework. In this exploration, we underscore the importance of considering exposure mechanisms through passive, consumptive, and active behaviors, along with contextual factors such as socio-economic status, demographics, and climate conditions. In this framework, elements like tourism, recreation, and leisure are associated with active participation.

Current literature employs various metrics to measure health and well-being, highlighting the necessity for standardized approaches and new methodologies to evaluate how study design affects outcomes. In conclusion, the studies reviewed indicate moderate evidence supporting a positive relationship between green environments and well-being, although significant positive effects are not consistently observed across all cases.

Ecosystem services play a vital role in enhancing human well-being through various pathways. The Millennium Ecosystem Assessment (MEA, 2005) identifies five key elements contributing to well-being: security, basic materials for a good life, health, good social relations, and freedom of choice and action. The concept of security encompasses not only the physical safety of individuals and their properties but also the broader assurance of access to essential resources and the ability to avert human-induced disasters. Basic materials for a good life include essentials like shelter, food, water, energy, income, assets, and access to goods.

Health is a central component of human well-being and is fundamentally dependent on the ecosystem's capacity to deliver healthy and adequate ecosystem services, such as clean water, nutritious food, and good air quality. The MEA framework categorizes ecosystem services into four groups: provisioning, regulating, cultural, and supporting services. Supporting services underpin the functioning of the other ecosystem services, facilitating essential processes like nutrient cycling and soil formation. Ecosystems also provide direct provisioning of goods, including food, water, and medicinal plants. Regulating services contribute to human well-being by controlling climate and flood dynamics. Cultural services impact health by offering opportunities for recreational activities and fostering aesthetic and spiritual connections, which enhance both physical and mental well-being. Engaging in recreational activities promotes active lifestyles, reducing the risk of diseases such as cardiovascular issues and obesity, while also supporting mental health, community cohesion, and a sense of identity.

The quality of the environment significantly influences human health; for instance, air pollution can exacerbate existing cardiovascular and respiratory conditions, particularly in older adults. Conversely, improvements in air quality and reductions in extreme temperatures can yield positive health outcomes. Direct interaction with nature has been shown to benefit health by enhancing cardiovascular and respiratory functions, decreasing the prevalence of diabetes and obesity, and improving psychological well-being. Access to green spaces, such as urban parks, fosters social interactions, thereby strengthening community bonds and positively affecting social relations.

This paper examines the health benefits provided by green and blue spaces, including urban parks, green areas, freshwater systems, and coastal zones. To achieve this, a literature review was conducted to explore how the natural environment influences various dimensions of well-being, with a specific focus on health and its determinants.

IV. Discussion

The passage you've shared provides a detailed analysis of the ecosystem services provided by freshwater ecosystems, particularly wetlands, and the challenges associated with their management in both developing and developed countries. It highlights the importance of these ecosystems for a wide range of cultural, commercial, and ecological functions, while also addressing the negative impacts of industrial agriculture, pollution, and urbanization. Several key themes and strategies emerge from the discussion on how to balance human needs with the preservation of natural systems.

First, freshwater ecosystems provide critical services, including water purification, flood regulation, habitat provision, and cultural benefits. The value of these services is substantial, as evidenced by studies that quantify their economic worth. While agriculture is seen as a provider of ecosystem services, industrialized farming often leads to environmental degradation. Practices associated with large-scale agriculture can diminish soil health, reduce biodiversity, and pollute water sources. There is a growing recognition of agroecology as a means to promote sustainable agricultural practices that work in harmony with natural ecosystems. This approach emphasizes soil health, recycling of materials, and the empowerment of local communities.

Wetland management is crucial, and the concept of "wise use" encourages sustainable practices that protect and restore these environments, ensuring they continue to provide their valuable services. The passage questions the effectiveness of investing in cleanup efforts for polluted water bodies while the root causes of pollution remain unaddressed, advocating for proactive measures to eliminate pollution drivers. Rapid growth of global populations and industrial activity poses challenges to the conservation of natural ecosystems. Balancing these demands with the need for environmental protection is crucial for sustainable development.

To address these challenges, integrated water resource management (IWRM) can help balance the demands of various sectors—agriculture, industry, and domestic use—while prioritizing the health of freshwater ecosystems. Promoting agroecology and organic farming can enhance soil health and biodiversity, reduce reliance on chemical inputs, and increase resilience to climate change. Education and support for farmers can facilitate this transition. Ecosystem-based adaptation strategies, such as restoring wetlands and reforesting, can mitigate flooding and protect communities in a cost-effective manner. Finally, strengthening regulations on industrial discharges and agricultural runoff can significantly reduce the nutrient loading that harms freshwater systems, ultimately leading to healthier ecosystems that can continue to support both human populations and biodiversity.

Schumacher's observation about the alienation of modern man from nature encapsulates a critical challenge in contemporary society: the prevailing view of nature as an adversary rather than an integral part of human existence. This mindset drives a relentless push to dominate and control the natural world, often leading to environmental degradation in the pursuit of short-term economic gains. The passage outlines the consequences of this approach, particularly through the examples of infrastructure development and industrial agriculture, and raises the question of whether viable alternatives to purely technological solutions exist. The emphasis on technological solutions often overlooks the inherent value of natural ecosystems. For example, while concrete structures can provide flood protection, they typically come with higher costs and fail to replicate the multifaceted benefits provided by healthy ecosystems, such as wetlands and mangroves. The ecological services these natural barriers provide—like storm surge protection and nursery habitats for marine life—are not easily quantifiable but are critical for community resilience.

Moreover, the conversion of natural environments for industrial use frequently benefits a small number of individuals or corporations at the expense of local communities. In the case of shrimp aquaculture in Sri Lanka, the socioeconomic impacts disproportionately affected traditional livelihoods while offering minimal benefits. This pattern is evident globally, where the costs associated with ecosystem destruction often fall on the poorest populations and future generations, who rely on these ecosystems for their survival. The issue of 'non-tradable public benefits,' which are essential ecosystem services that do not enter the market economy, is particularly concerning. Politicians and businesses typically operate on short time scales, failing to account for the long-term consequences of ecosystem degradation. This shortsightedness allows for continued exploitation of natural resources, transferring economic benefits from many to a privileged few.

In light of these challenges, viable alternatives to technological responses can be explored. Ecosystem-based management integrates ecological health into resource management decisions. By prioritizing the conservation and restoration of ecosystems, communities can benefit from the natural services these systems provide, such as clean water, flood protection, and biodiversity. Community-led conservation engages local populations in the stewardship of their natural resources, fostering a sense of ownership and responsibility that often results in more effective conservation outcomes. Payment for ecosystem services (PES) incentivizes the protection of ecosystem services by compensating landowners and communities for maintaining or restoring natural habitats. PES schemes help align economic incentives with environmental health, ensuring that the benefits of healthy ecosystems are recognized and rewarded.

Integrated water resource management (IWRM) promotes a holistic approach to managing water resources, considering the interdependencies between water, land, and ecosystems. By balancing the needs of different sectors and ensuring sustainable use of water resources, IWRM can help protect vital ecosystems while meeting human demands. Transitioning to agroecological practices can enhance food production while preserving ecosystem health. By focusing on ecological principles, such as crop diversity and soil health, agroecology aims to create resilient agricultural systems that support local communities without degrading the environment. Incorporating natural elements into urban planning—such as green roofs, permeable pavements, and urban forests—can mitigate the impacts of climate change and reduce reliance on traditional engineering solutions. These practices enhance urban resilience while providing ecological benefits.

In conclusion, the challenges posed by modern society's disconnection from nature require a paradigm shift in how we view and interact with the natural world. Viable alternatives to technological responses exist and often prioritize ecological health, social equity, and community resilience. By recognizing the intrinsic value of ecosystems and incorporating their services into economic and developmental frameworks, societies can move toward a more sustainable future that respects both people and nature. This approach not only mitigates the adverse effects of environmental degradation but also fosters a deeper connection between humans and the natural world, ultimately leading to a more balanced and sustainable coexistence.

Abstract

Since the second half of the twentieth century, the atmosphere, as the main component of the environment, has undergone significant changes due to the impact of anthropogenic factors, which have resulted in global climate change and its impact on humans and ecosystems. The consequences of climate change are often complex in nature, which makes it particularly difficult to determine the cause-and-effect relationship between them. The paper presents the results of the monitoring of atmospheric polluting components for Tbilisi City territory (period of March 2023), when there was observed smog, accompanied by a sharp worsening of visibility and the synoptic situation, causing the mentioned condition was determined. The main aim of the study is detection of atmospheric pollution level in Tbilisi, and assessment of anthropogenic sources. Studies have revealed, that the main synoptic situation for Tbilisi, during which the total pollution increases, is a "high-pressure trough", which is mainly associated with the stationary anticyclone of Kazakhstan, Western Siberia, or Eastern Siberia. During the mentioned situation, the concentration of polluting substances in the atmosphere (for Tbilisi city) increases. In almost every related case: Wind speed at the surface of the earth is less than 5 m/s; The influence of the front and stream currents is not observed, and the wind speed is also reduced at the height; Turbulent mixing is weak at 1-3 m/s; Cases of inversion and isotherms are common. Under these conditions, the level of pollution in the ground layer increases as a result. In the paper, the dynamics of quantitative change of individual pollutant sources, and aerosols in the atmosphere is revealed. Research has established, that the ecological condition of the atmosphere depends on the specificity and intensity of the pollution source, on physical-geographical and meteorological conditions (inversion, isothermy), and synoptic situations, typical for Tbilisi.

Keywords: Climate change, smog, synoptic situation, Tbilisi, pollution

I. Introduction

Starting with the second part of the 20th century, atmosphere, as a main component of the environment underwent substantial changes due to impact of anthropogenic factors that as a consequence caused global climate changes and its influence on human and ecosystem [1].

Polluting agents emitted in the troposphere not only impact on human and ecosystem, but also generate harmful substances. There are two factors of atmosphere pollution, namely natural and anthropogenic-technogenic factors.

One of biggest problems of the modern world is a global environmental pollution that causes climate changes [2]. Following civilization development, a human modifies environment and ecosystem, in general. All this is resulted in deterioration of social environment, human health status that is already of global nature and covers the entire planet [3, 4, 5].

Elemental processes become more frequent and intense along with climate changes. Intensification of some of these events is related to the change of global climate system.

During the past century, in parallel with upcoming of so-called "era of industrialization", the problem of atmosphere pollution became relevant in the entire world, including Georgia. Alongside with technological progress, the number of harmful emissions has continuously increased that caused surpass of maximum permissible concentrations of separate components entering the atmospheric air [6, 7].

The last decade clearly showed that under conditions of demographic explosion and intense development of manpower the tomorrow of the Earth and its future in general, mostly depends on the fact how we can protect the natural environment from anthropogenic impact. That is why the environmental protection problem got an extremely actual role among the most acute problems facing the mankind today [8].

Climate change results are frequently of integrated nature that especially complicates establishment of cause-and-effect relationship between them [9]. The scientific literature has repeatedly studied the issues of atmospheric circulation and dispersion of air pollution [10], effects of atmospheric processes on smog formation [11], impact of meteorological parameters of atmospheric pollution [12], etc.

The article represents the research results of monitoring of Tbilisi atmosphere polluting ingredients (2022-2023, March), when a smog accompanied by rapid deterioration in visibility was recorded at the territory of city. Synoptic situation causing the mentioned state was established.

The research **goal** is a qualitative and quantitative assessment of anthropogenic sources of Tbilisi city atmosphere pollution; establishment of quality conditions of atmospheric air; quantitative assessment of main atmosphere polluting ingredients: solid suspended particles (PM10 and PM2.5), sulfur dioxide (SO_2) and carbon oxide (CO) with the use of monitoring data, identification of atmosphere pollution level and its impact on human health under Tbilisi conditions.

It was established by studies that so-called high-pressure baric field, which is mainly related with stationary anticyclone of Kazakhstan, western Siberia or eastern Siberia is the most characteristic synoptic situation for Tbilisi, during which the total pollution increase occurs. During the mentioned situation, atmospheric concentrations of polluting substances (Tbilisi city) increase almost in all cases. Wind velocity near the Earth surface is less than 5 m/sec; front and stream flow effect is not observed, wind velocity is decreased at a height, as well; turbulent mixing is weak and equals to 1-3 m/sec; there are frequent cases of inversion and isothermy. Under the mentioned conditions, pollution level in the surface layer increases.

Dynamics of quantitative changes of aerosols emitted in the atmosphere from separate polluting sources is revealed in the work.

It is established by the study that ecological state of the atmosphere depends on peculiarity and intensity of pollution source, physical-geographic and meteorological conditions (inversion, isothermy), and synoptic situations under complex microclimate and physical-geographic conditions of Tbilisi city. The mentioned state results in increase of surface layer pollution level.

Meteorological conditions of atmosphere pollution

Tbilisi is located in the eastern Georgia, in the Tbilisi hollow, and is spread on both embankments of Mtkvari (Kura) River, at 380-600 meters height from the sea level.

Complex terrain of Tbilisi territory predetermines peculiarities of its natural environment. It is generally represented in the form of hollow. Terrace system of Mtkvari River, the nature of its horizontal and vertical dissection puts the city-planning measures within narrow bounds, complex topographic conditions established thereof hinders proportional territorial growth of the city. City expansion put its relief form under influence of anthropogenic factors, and as a consequence drastically changed its morphometrical characteristics. Terrace forms of city building modified original form of water-dividing ridges and slopes [13, 14].

Aerosols are non-uniformly distributed in Tbilisi that depends not only on distribution of the pollution focuses, but also on meteorological conditions (inversion, isothermy). The main among meteorological processes is an atmosphere circulation, when aerosols are spread in both, vertical and horizontal directions. Aerosols transfer intensity depends on relief, meteorological conditions and wind regime.

Dissipation or diffusion of aerosols generated by the different sources occurs very intensely by means of turbulent mixing peculiar for surface air. In this case aerosols are dissipated and their concentration is getting smaller, that depends on atmosphere stratification [4, 5].

It is obvious that duration and repetition of meteorological conditions cause severe pollution of Tbilisi air compared to those cities, which are characterized by relatively less duration and repetition of elemental meteorological events [13].

Complex terrain and meteorological conditions of Tbilisi substantially change characteristics of general circulation of atmosphere that causes peculiar character of aerosols distribution, for which sustainable condition of atmosphere is especially important. Duration of aerosols availability in the atmosphere is considerably influenced by character of the vertical profile of meteorological elements (temperature, wind, humidity).

Wind velocity is reduced by 20-30% in the city, compared to suburban areas, that is caused by air flow inhibition between buildings. Above buildings the wind velocity rapidly increases (approximately according to logarithmic law). In the cases, when temperature inversion is not recorded in Tbilisi, wind velocity at heights may increase up to the value, which exceeds velocity peculiar for open places and jet flow may originate at heights. Wind direction and velocity are changeable enough, especially during strong winds.

Convection development, which in the surface layers is accompanied by air mass shift towards city center, may be associated with a "heat island". The observations show that in case of light wind, there are originated air flows routed to the city center with 2-3 m/sec velocity, and ascending vertical flows headed to the central part. These factors promote water steam condensation and precipitation enhancement in the city [14, 15].
